7.8 Liver Metabolism and Hepatic Toxicity Effects of Ammonium Perchlorate

No evidence of liver toxicity, as judged by blood chemistry tests, was observed in a group of nine human volunteers who ingested approximately 0.14 mg of perchlorate/kg/day as potassium perchlorate for 14 consecutive days [976]. Similar results were reported by Greer et al., [977] in a study of 37 volunteers who consumed up to $0.5 \text{ mg ClO}_4^- \text{ kg}^{-1} \text{ d}^{-1}$ also for 14 days.

A study by Crump et al. [993] examining 162 school-aged children from three cities in northern Chile with different perchlorate concentrations in the drinking water (up to $100\text{--}120 \mu\text{g/L}$) found no indications of altered liver function among the children, as measured by serum aspartate aminotransferase (AST), alkaline phosphatase, or lactate dehydrogenase (LDH) activities.

Godley and Stanbury [1032] reported no evidence of liver toxicity in a series of 24 hyperthyroid patients treated with potassium perchlorate (600 mg , prox. 6 mg perchlorate $\text{kg}^{-1} \text{ d}^{-1}$) for up to 52 weeks. However, it is not clear what tests were conducted to monitor effects on the liver or how frequently such tests may have been conducted.

An animal feeding study in rats found that the administration of AP in drinking water at doses up to 8.5 mg perchlorate $\text{kg}^{-1} \text{d}^{-1}$ for up to 90 days caused no significant alterations in liver weight, in the gross or microscopic appearance of the liver, or in serum transaminase activities [967].

No effects on liver weight were reported in 14- and 90-day studies using mice that were administered up to 25.5 mg perchlorate/kg/day in their drinking water in the form of the ammonium salt [966].

7.8.1 Metabolic Effects

No studies were sourced regarding the metabolic effects and enzyme disturbances in humans after oral exposure to perchlorate.

Researchers in India conducted a number of animal studies investigating the metabolic effects of perchlorate in rats who were given 500 mg $\text{kg}^{-1} \text{d}^{-1}$ of potassium perchlorate, sodium perchlorate, or AP via daily gavage for 45 days [1033–1038]. They found that perchlorate increased protein metabolism (increased liver arginase activity and serum urea levels). It also altered carbohydrate metabolism (decreased serum glucose and increased liver and kidney glycogen levels, reflecting increased activity of aldolase, lactate dehydrogenase, and glycogen synthase, and decreased activity of glucose-6-phosphatase and glycogen phosphorylase), modified lipid metabolism (increased cholesterol, triglyceride, and phospholipid, and decreased free fatty acid levels, reflecting decreased activity of lipase and phospholipase). They also found that perchlorate reduced the activities of mitochondrial enzymes involved in cellular respiration, apparently due to changes in lipid composition of mitochondrial membranes (increased cholesterol and decreased phospholipid) reducing membrane fluidity.

Other studies reported no effect on serum glucose in rats exposed to 0.1% potassium perchlorate (approximately 175 mg perchlorate/kg/day) in their drinking water for 25 days [1039]. No effects were observed on serum glucose levels in rats that were exposed to up to 8.5 mg of perchlorate/kg/day as AP in the drinking water for up to 90 days [967].

7.9 Renal Toxicity and Ammonium Perchlorate Excretion in Urine

7.9.1 Renal Effects of AP

Limited information exists regarding renal effects of perchlorate in humans. Two studies in euthyroid volunteers who ingested up to 0.5 mg $\text{ClO}_4^- \text{kg}^{-1} \text{d}^{-1}$ as the potassium salt for 14 days found no evidence of renal effects, as judged by standard clinical chemistry tests [976, 977]. Also, no alterations in blood urea nitrogen (BUN) concentration or in serum creatinine levels were observed in a group of 60 school-aged children from

northern Chile exposed to perchlorate in their drinking water at concentrations up to 100–120 µg/L [993].

In 14- and 90-day drinking water studies in rats, doses of up to 8.5 mg kg⁻¹ d⁻¹ produced no significant alterations in kidney weight or in gross or microscopical appearance of the kidneys [967]. In addition, kidney function, monitored by measurements of BUN and serum creatinine, was not affected by exposure to perchlorate [967]. A similar study in mice also found no effects of AP on kidney weight following 14 or 90 days of exposure to up to 25.5 mg ClO₄⁻ kg⁻¹ d⁻¹, however, kidney function tests were not performed [966].

7.9.2 Perchlorate in the Urine

Almost all perchlorate that enters the body via eating or drinking is excreted in the urine. Urine sampling and analysis of large populations are, therefore, a lot easier to do than blood analysis from a certain population group. Thus, it is of particular interest to find a correlation between perchlorate excreted in the urine and potential thyroid gland interference caused by high perchlorate levels.

The potential relationship between urinary levels of perchlorate and serum levels of TSH and total thyroxine (T₄) was studied in 2299 men and women, ≥12 yr of age, participating in the NHANES during 2001–2002 [1040, 1041]. Perchlorate in the urine was not a significant predictor of T₄ or TSH levels in men. However, for women overall, perchlorate was a significant predictor of changes in both T₄ and TSH. For women with low urinary iodine <100 µg/L, perchlorate was a significant negative predictor of T₄ ($p < 0.0001$) and a positive predictor of TSH ($p = 0.001$). For women with higher urinary iodine ≥100 µg/L, perchlorate was a significant positive predictor of TSH ($p = 0.025$) but not T₄ ($p = 0.550$). These associations of perchlorate with T₄ and TSH were coherent in direction and independent of other variables known to affect thyroid function, however, they were detected at perchlorate trace exposure levels that were unanticipated based on previous studies.

A simple two-compartment first-order pharmacokinetic model that predicts concentrations of perchlorate in blood and urine was constructed and validated [1042]. The model was validated using data from a high-dose experiment in humans where doses and resulting concentrations of perchlorate in blood and urine were well documented. Specifically, data were available for individuals who had been dosed at 0.5, 0.1, and 0.02 mg kg⁻¹ d⁻¹ for 14 consecutive days. This was a significantly higher than the average background dose, which is estimated to be less than 0.0001 mg kg⁻¹ d⁻¹. The average measured urine concentration in the high-dose regime during the experiment was 15.4 mg/L compared with an average prediction of 17.3 mg/L. In the medium-dose regime, the average measured was 3.0 mg/L compared with 4.1 mg/L predicted. In the low-dose regime, the average measured was 0.53 mg/L compared with 0.68 mg/L predicted.

7.10 Ammonium Perchlorate in the Blood

Severe hematological effects have been found in several cases where hyperthyroid patients were treated with potassium perchlorate for a long time. Some patients developed aplastic anemia, which was characterized by drastic reductions in circulating granulocytes, erythrocytes, and thrombocytes, and a lack of erythropoietic and granulopoietic cells in the bone marrow. Aplastic anemia was the cause of death in most of the documented fatalities associated with treatment of thyrotoxicosis using potassium perchlorate. All of the documented cases of aplastic anemia and agranulocytosis were females (Graves' disease, the most common cause of hyperthyroidism, is far more common in women than in men).

For epidemiological studies, it is common practice to analyze for AP concentrations in body fluids. It has been attempted to establish a correlation between AP concentration in the blood and in other body fluids. For instance, for worker health monitoring and workplace surveillance, it would be a lot easier to rely on saliva or urine samples than having to take blood samples before and after work shifts.

Thyroid gland and blood hematology effects of occupational exposure to perchlorates was assessed by measuring ambient air concentrations of total and respirable perchlorate particles in the workplace. Systemic absorption was also assessed by measuring urinary perchlorate excretions. Airborne exposures ranged from 0.004 to 167 mg total particulate perchlorate per day. Urinary perchlorate measurements demonstrated that exposure to the airborne particulate perchlorate resulted in systemic absorption. Workers were grouped into four exposure categories with a mean absorbed perchlorate dosages of 1, 4, 11, and 34 mg perchlorate per day. No clinical evidence of hematological abnormalities was found in any exposure group. The blood-cell counts were normal in all groups, thus indicating no evidence of hematotoxicity in this exposure range [981]. This is also supported by animal studies using higher doses. The absence of evidence of an effect on blood cells from occupational airborne perchlorate exposure at a mean absorption of 34 mg/d demonstrates a NOAEL that can assist in the evaluation of human health risks of the general population from environmental perchlorate contamination.

Hematological parameters were evaluated in an epidemiological study of school-age children from three cities with different concentrations of perchlorate in drinking water in northern Chile [993]. The city with the highest perchlorate concentration was Taltal, 100–120 µg perchlorate/L (ppb), where water is drawn from the city of Chañaral had 5–7 µg/L. Perchlorate was not detected in water from the city of Antofagasta. Analysis of CBC showed no significant differences between the three groups of children.

A liquid chromatography – tandem mass spectrometry (LC-MS/MS) method was optimized to analyze for perchlorate in blood sera and plasma samples from 84 donors [1043]. In addition, 15 volunteers provided saliva and serum samples concurrently, to enable assessment of the ratio of perchlorate in these two matrices. Perchlorate concentrations in serum and plasma ranged from below the limit of

quantitation (0.05 ng/mL) to a maximum of 7.7 ng/mL. The mean and median concentrations of perchlorate in 84 serum and plasma samples were 0.32 and 0.17 ng/mL, respectively. No significant difference existed in perchlorate concentrations between serum and plasma. Analysis of paired saliva and serum samples revealed a significant positive correlation for log-normalized perchlorate concentrations ($r^2 = 0.60$) and perchlorate concentrations themselves ($r^2 = 0.86$). The mean saliva : serum concentration ratio of perchlorate was 14 : 1.

7.11 Establishment of a RfD for Ammonium Perchlorate

Typically a NOAEL or a LOAEL for potentially toxic chemicals is identified using published data or government-commissioned carefully controlled experiments on which the RfD can be based.

The EPA has issued a provisional RfD that would restrict the discharge of AP-containing waters to less than 1 ppm. This may significantly increase the cost of wastewater disposal at rocket propellant installations where the old propellant is demilitarized by high-pressure water washout and attempts are made to recycle some of the materials. It was estimated that the demil of 1200 Minuteman III first and second stage motors will require the processing of 15900 metric tons (35 million pounds) of propellant consisting mostly of AP (68–73% AP). As of 1998, an additional 57 SRMs were awaiting disposal via water washout. In addition to this burden, AP waste streams accumulate at AP production sites, rocket propellant mixing sites, and static firing test sites.

The EPA, which has responsibility for establishing national drinking-water standards, issued a draft risk assessment of perchlorate in 2002 [1044]. In February 2005, the EPA established its official RfD of perchlorate, which was set at $0.0007 \text{ mg ClO}_4^- \text{ kg}^{-1} \text{ d}^{-1}$, and translated that number to a Drinking Water Equivalent Level (DWEL) of 24.5 ppb. This level is consistent with the recommended RfD included in the National Academy of Sciences' January 2005 report. An RfD is a scientific estimate of a daily exposure level that is not expected to cause adverse health effects in humans. See the website [1045] (*Perchlorate and Perchlorate Salts*), which provides a summary of EPA actions. However, as of 2005, the assessments have come under criticism on the grounds that the conclusions presented in them were based on flawed scientific studies and that not all available data had been incorporated appropriately into them. In view of the controversy surrounding the concentration at which perchlorate should be regulated, Government agencies in the US then asked the NRC to independently assess the adverse health effects of perchlorate ingestion from clinical, toxicologic, and public-health perspectives. A committee at the NRC has subsequently evaluated the data and issued recommendations [934]. The NRC Committee suggested that animal test data should **not** be used as the basis of a perchlorate risk assessment.

NAS based its derivation of the RfD on the findings of a study by Greer et al. [977]. The RfD was based on a no-observed-effect level (NOEL) of $0.007 \text{ mg ClO}_4^- \text{ kg}^{-1} \text{ d}^{-1}$ for thyroidal uptake of RAIU in 37 healthy (euthyroid) volunteers (16 males, 21 females) who consumed potassium perchlorate in drinking water in doses of 0.007, 0.02, 0.1, or 0.5 $\text{mg ClO}_4^- \text{ kg}^{-1} \text{ d}^{-1}$ for 14 days. In 24 subjects, thyroidal uptake of RAIU was measured eight and 24 hours after each administration of radioactive iodine on exposure days 2 and 14 and also 15 days after the last exposure. To estimate daily iodine intake, 24-hour urine samples were collected. Free and total T4, T3, and TSH were sampled 16 times throughout the study. The RfD was calculated by dividing the NOEL of $0.007 \text{ mg ClO}_4^- \text{ kg}^{-1} \text{ d}^{-1}$ for inhibition of radioiodide uptake and serum hormone levels by an uncertainty factor of 10.

In January 2009, the EPA issued a health advisory to assist state and local officials in addressing local contamination of perchlorate in drinking water [1046]. The interim health advisory level of $15 \mu\text{g/L}$, or ppb, is based on the RfD recommended by the NRC of the National Academy of Sciences.

In ATSDR's *Toxicological Profile for Perchlorates* [1047], which is a 299-page comprehensive summary of toxicity data for perchlorate and perchlorate salts, Section 1.9 notes that "The EPA is currently undertaking efforts to make a determination as to whether or not a national primary drinking water regulation (NPDWR) is needed for perchlorate. To make this determination, EPA is evaluating information to more fully characterize perchlorate exposure to determine if regulation of perchlorate in drinking water would represent a meaningful opportunity for reducing risks to human health as required under the Safe Drinking Water Act (SDA)." More recently, the EPA has presented a Preliminary Regulatory Determination on Perchlorate in the Federal Register (73FR198:60262-60282) stating that the EPA has determined that an NPDWR for perchlorate would not present "a meaningful opportunity for health risk reduction for persons served by public water systems". However, this position was reversed under pressure from some of the representatives and senators in Congress.

Section 1.9, as well as Chapter 8 of the *Toxicological Profile* notes that the "EPA's Office of Solid Waste and Emergency Response has provided guidance for perchlorate that indicates that the RfD and its corresponding DWEL of 24.5 ppb are respectively the recommended **to be considered** (TBC) value and the preliminary remediation goal (PRG) for clean up under the *Comprehensive Environmental Response, Compensation, and Liability Act* of 1980 (CERCA)." Table 8-1 of the profile also lists the existing PRG. However, the EPA's Preliminary Regulatory Determination on Perchlorate also notes that the EPA will replace its existing PRG of 24.5 ppb with a health reference level (HRL) of 15 ppb for drinking water. The EPA explained that the existing PRG was calculated with the assumption that all exposure comes from groundwater at National Priorities List (NPL) sites, whereas the HRL was calculated using the RfD of $7 \mu\text{g/kg/day}$ and a relative source contribution from water, which was relative to a calculated contribution from food. The EPA states that the final HRL will be the basis for a health advisory in the health advisory document that the agency expects to issue when the

final Regulatory Determination on Perchlorate is released. The EPA notes that it may be appropriate to use the HRL as a TBC value in developing potential clean-up levels for perchlorate NPL sites.

ATSDR summarized its Toxicological Profile for Perchlorates [1048] in a two-page summary of toxicity data for perchlorate and perchlorate salts in September 2008. It was amended by an addendum [1049] in October 2008.

On 10 October 2008, the EPA issued a preliminary determination for perchlorate in the Federal Register (73 FR 60262) stating that there was not a “meaningful opportunity for health risk reduction” through a national drinking water regulation. As of 2009, the EPA has received more than 32000 comments on the notice and is now requesting additional input before making a final regulatory determination on whether to issue a national regulation for perchlorate in drinking water. In response to stakeholder comments that provided additional scientific evaluation of the information the EPA used to make its preliminary determination, in January 2009 the EPA announced that it planned to seek additional input from the NRC on assumptions regarding the possible effects of perchlorate on infants and young children. Around the same time, the EPA’s Office of Water published an interim health advisory for perchlorate that included a health advisory level of 15 parts per billion. This interim health advisory level took into account exposure from food as well as drinking water for pregnant women and their fetuses (the most sensitive life stage identified by NRC). The advisory provided informal technical guidance to assist state and local officials in protecting public health where perchlorate contamination of drinking water has occurred. Meanwhile, the EPA evaluated the opportunity to reduce risks through a national drinking water standard (DWS). Following the establishment of the interim health advisory, the EPA’s Office of Solid Waste and Emergency Response withdrew its PRG for perchlorate of 24.5 ppb. In its place, the EPA recommended the interim health advisory level of 15 ppb be used as the PRG when assessing sites for clean-up under CERCLA.

On 8 January 2009, the EPA issued an interim health advisory of 15 parts per billion (ppb) to assist state and local officials in addressing local contamination in drinking water. This interim health advisory of 15 ppb also replaced the existing PRG goal of 24.5 ppb (established in 2006, EPA Memorandum 26 January 2006) used to establish clean-up levels for perchlorate at Superfund sites. The advisory level was based on earlier recommendations by the NRC, which functions under the National Academy of Sciences. States have the right to establish and enforce DWSs and the EPA encourages state-specific situations to be addressed at local levels. The EPA expects to issue a final health advisory concurrent with the final regulatory determination for perchlorate.

In August 2009, the EPA published a notice that it would not seek additional input from the NRC and instead was seeking public comment on additional approaches for interpreting the available data on the level of health concern, the frequency of occurrence of perchlorate in drinking water, and the opportunity for health risk reduction through a national DWS.

In April 2010, the EPA's Office of Inspector General released a report that reviewed and critiqued the risk assessment process and procedures used by the EPA to develop and derive the perchlorate RfD [1050]. As of July 2010, the EPA had not yet made a final decision as to whether it would establish a regulatory standard for perchlorate in drinking water.

Some of the EPA's actions were critiqued by industry representatives as lacking scientifically correct foundations and as causing unnecessary expenses to the industry. The benefit : risk evaluation of issuing new regulations continued for a very long time.

The extent to which perchlorate, which occurs naturally and as an industrial contaminant, should or should not be regulated has become controversial [1051]. A number of inconsistent conclusions have been drawn based on thyroid hormone serum concentrations, urinary iodine concentrations, and perchlorate exposure among women participating in the 2000–2001 NHANES and based on a body of epidemiologic and clinical evidence reporting no associations between effects on thyroid hormones and similar or much higher levels of perchlorate exposure. For example, studies associating perchlorate with thyroid effects at low exposures did not control for anti-thyroid agents with modes of action that differ from that of perchlorate, such as some organochlorines. Available evidence does not support a causal relationship between changes in thyroid hormone levels and current environmental levels of perchlorate exposure but does support the conclusion that the EPA's RfD for perchlorate is conservatively health-protective. Potential perchlorate risks are unlikely to be distinguishable from the ubiquitous background of naturally occurring substances present at much higher exposure levels that can affect the thyroid via the same biological mode of action as perchlorate such as nitrate and thiocyanate.

7.11.1 Legislative Actions Regarding Perchlorate

In view of the contamination of numerous drinking water sources by perchlorate in California, legislation (S. 24, S. 2298, H.R. 4798 [109th Congress]) was introduced in 2006 (but not enacted) to accelerate the remediation of polluted water sources and to inform the general public about the hazards of perchlorate in drinking water.

Perchlorate contamination received a lot of attention in the 110th Congress [1052]. Responding to the EPA's decision not to require further monitoring for perchlorate as an unregulated contaminant, S. 24 was introduced to require community water systems to test for perchlorate and disclose its presence in annual consumer reports. S. 150 and H. R. 1747 would require the EPA to establish a DWS for perchlorate. In September 2008, the Senate Environment and Public Works Committee reported S. 24 (S. Rept. 110–483) and S. 150 (S. Rept. 110–484). Another bill, H. Con. Res. 347, expresses the intent of Congress to ensure that the CDC and the FDA should take action to educate the public on the importance of adequate iodine intake. (Iodine is protective against perchlorate exposure.) The House Energy and Commerce Committee's En-

vironment and Hazardous Substances Subcommittee marked up and approved H. R. 1747 in late 2007. Other legislative actions relating to perchlorate contamination were: 110th Congress 2007–2008 S. 24 *Perchlorate Monitoring and Right-to-Know Act of 2008* [1053]

111th Congress 2009–2010 H.R. 3481: *Lower Colorado River Protection Act*

111th Congress 2009–2010 H.R. 3206: *Safe Drinking Water for Healthy Communities Act of 2009*

111th Congress 2009–2010 H.R. 2316: *Inland Empire Perchlorate Ground Water Plume Assessment Act of 2009*

111th Congress 2009–2010 H.R. 4252: *Inland Empire Perchlorate Ground Water Plume Assessment Act of 2010*

The toxicological database on ClO_4^- as of March 1997 was determined by an expert peer-review panel to be inadequate for the purpose of deriving an oral RfD. For example, little or no experimental data existed on the sub-chronic, reproductive, or developmental toxicity of perchlorate. To fill gaps in the toxicological database, eight animal studies were designed by a government-industry consortium that included the EPA and the Air Force Research Laboratory (AFRL). These studies were performed in 1997 and 1998. Upon review of complete study reports from four of the studies and incomplete data from the other two, the EPA/National Center for Environmental Assessment (NCEA) issued a document in December 1998. This stated that the critical effects were hormone and histology data from the neurodevelopmental/behavioral toxicity study that had been performed in rats. An RfD was proposed based upon the observation of thyroid-follicular-cell hypertrophy in five-day-old pups of dams given perchlorate in drinking water at 0.1 mg/kg-day (the lowest dose tested) in this study [1054].

Getting tired of waiting for the federal EPA to establish a drinking water safe limit for perchlorate, several states went ahead and established their own limits. California proposed an enforceable limit of 6 ppb for perchlorate in drinking water, four times more stringent than the EPA's standard of 24 ppb. The State of Massachusetts' perchlorate RfD and DWS are considerably lower and more health-protective than related values derived by several other agencies. Before setting this limit, the Massachusetts Department of Environmental Protection scientists, with input from a science advisory committee, assessed a wide range of perchlorate risk and exposure information [1055]. Health outcomes associated with iodine insufficiency were considered, as were data on perchlorate in drinking water disinfectants. A health protective RfD (0.07 $\mu\text{g}/\text{kg}/\text{day}$) was derived using an uncertainty factor approach with perchlorate-induced iodide uptake inhibition as the point of departure. The DWS (2 $\mu\text{g}/\text{L}$) was based on risk management decisions weighing information on perchlorate health risks and its presence in certain disinfectant solutions used to treat drinking water for pathogens.

In February 2011, the Obama administration announced that the EPA will establish the "first federal DWS for a toxic rocket fuel ingredient linked to thyroid problems

in pregnant women and young children.” The EPA issued a *Final Regulatory Determination* for Perchlorate but the standard itself could take up to two years to develop, the EPA stated. This decision reversed a 2008 preliminary determination and considered input from almost 39000 public commenters on multiple public notices (May 2007, October 2008, and August 2009) related to perchlorate. Pentagon officials have spent years questioning the EPA’s assessment of perchloate risk but have denied influencing the agency’s decisions. The military could face liability for contaminating water during rocket and missile testing due to the standard forcing water agencies around the country to clean up the pollution caused by this (see [1056–1062] also).

In 2018, Docket EPA-HQ-OW-2018-0780 proposed an upper limit of 56 ppb for perchlorate in drinking water. It was argued that a less restrictive limit for perchlorate in drinking water would disregard the risks to children’s health, ignore the latest results of scientific research, and fail to follow the requirements of the Safe Drinking Water Act to use the best available peer-reviewed science for setting DWSs.

7.11.2 Economic Impacts of New Perchlorate Regulations

Compliance with the new perchlorate regulations increases the cost of producing, handling, and disposing of AP and other perchlorates. The economic impact of the new regulations on the AP and solid rocket propellant industry has not yet been quantified [1063]. The impact of overly restrictive perchlorate regulations on the drinking water industry could be substantial [1064].

7.12 Carcinogenicity of Ammonium Perchlorate

The thyroid gland is the main target organ for perchlorate toxicity in animals. The thyroid changes caused by perchlorate in animals may lead to tumors in the thyroid after a long period or high-concentration exposure. This has occurred after administering high amounts (928 to $2573 \text{ mg ClO}_4^- \text{ kg}^{-1} \text{ d}^{-1}$) of perchlorate to the animals [1065]. The data from these studies are limited for assessment of carcinogenicity, however, because only a high dose level was used. Still, it was evident that the main target of toxicity was the thyroid gland as thyroid adenomas and/or carcinomas were observed in some of the animals. The NAS concluded that based on the understanding of the biology of human and rodent thyroid tumors, it is unlikely that perchlorate poses a risk of thyroid cancer in humans. Perchlorates have not been classified for carcinogenic effects by the Department of Health and Human Services (DHHS) or the International Agency for Research on Cancer (IARC). The EPA has determined that perchlorate is not likely to pose a risk of thyroid cancer in humans, at least at doses below those necessary to alter thyroid hormone homeostasis. This is based on the hormonally-mediated mode of action in rodent studies and differences seen across species in thyroid function.

A 2001 study found no significant association between perchlorate in drinking water and the prevalence of thyroid diseases or thyroid cancer residents in Nevada counties [1066]. However, no information was available on age, gender, ethnicity, iodine intake, and other risk factors. A study of cancer among residents of San Bernardino County, California, was limited by mixed exposures and lack of correction for potential other contributing factors [1067].

7.13 Teratogenicity of Ammonium Perchlorate

A developmental toxicity study was conducted to evaluate the embryo-fetal toxicity and teratogenic potential of AP in New Zealand white rabbits [1068]. Pregnant rabbits were given continual access to AP in drinking water at target doses of 0, 0.1, 1, 10, 30, and 100 mg kg⁻¹ d⁻¹ on gestation days six through 28. The actual consumed doses in the study were 0, 0.1, 0.9, 10.4, 30, and 102 mg kg⁻¹ d⁻¹. The rabbits were sacrificed on gestation day 29 and fetuses were examined for developmental alterations. In addition, blood was collected from does for determination of serum TSH, triiodothyronine (T3), and thyroxine (T4) levels and the thyroid was subjected to histopathologic examination. No maternal deaths were attributed to perchlorate exposure. The litter averages for corpora lutea, implantations, litter sizes, live and dead fetuses, percent dead or resorbed conceptuses, and fetal body weights were comparable and did not differ significantly in the six-dose groups. The maternal thyroid was the target organ for AP in this study. Increased incidence of thyroid follicular hypertrophy was observed in does treated with ≥ 10 mg kg⁻¹ d⁻¹ perchlorate and significantly decreased T4 was observed in does treated with ≥ 30 mg kg⁻¹ d⁻¹. Based on these data, the maternal NOAEL for AP was 1 mg kg⁻¹ d⁻¹. The developmental NOAEL for AP was found to be 100 mg kg⁻¹ d⁻¹ for rabbits.

In order to study the neurodevelopmental effect of AP-caused hypothyroidism, a neurobehavioral test for spontaneous locomotor activity was used to assess rat pups following pre- and neo-natal exposure to perchlorate [1069]. Pregnant dams were exposed to one of five doses of AP in their drinking water (0, 0.1, 0.3, 1.0, 10 mg mL⁻¹ kg⁻¹) beginning two weeks prior to gestation through to PND 10. The statistically reliable results indicated increased activity at older ages and reduced activity from the start of a given test session to the end of the session. Overall, the results suggest there was not a significant change in general locomotor activity due to pre- and neonatal perchlorate exposure at the doses tested.

Pregnant Sprague-Dawley rats were administered AP via their drinking water at doses of 0 or 1 mg ClO₄⁻ kg⁻¹ d⁻¹ from GD 2 to PND 21 [1070]. Cross-fostering was done on PND 1, such that four groups of pups were formed: never exposed, exposed in utero and via maternal milk, exposed only in utero, and exposed only via maternal milk. The results suggest that: (1) exposure in utero to perchlorate at the dose tested had little or no impact on serum levels of thyroid hormone and TSH measured in pups on PND 10,

(2) the changes in serum thyroid hormone and TSH levels seen in PND 10 pups exposed both in utero and via maternal milk appeared to be completely due to postnatal exposure to perchlorate through lactation, and (3) perchlorate could be acting directly on the pups' thyroid and/or may be limiting the availability of iodide to nursing pups by inhibiting NIS in breast tissue.

Perchlorate seeped into the aquifer extending from the Israel Military Industries plant in Ramat Hasharon. T4 levels in human newborns from mothers living in areas with very high ($\leq 340 \mu\text{g/L}$, $n = 97$), high ($42\text{--}94 \mu\text{g/L}$, $n = 216$) and low ($< 3 \mu\text{g/L}$, $n = 843$) levels of perchlorate did not reveal significant differences in T4 levels among the three groups [1071]. Levels of perchlorate in blood from donors living in the three areas were used as proxy indicators of exposure. Respective blood perchlorate levels in the very high, high, and low exposure proxy groups were 5.99, 1.19, and $0.44 \mu\text{g/L}$. Blood samples from the newborns collected at the age of 36 to 48 hours did not reveal significant differences in T4 levels among the three groups. Mean T4 values in the very high, high, and low exposure groups were 13.9, 13.9, and $14.0 \mu\text{g/L}$, respectively. In addition, neither birth weight nor gestational age was significantly different among the three groups. Although individual iodine measures were not conducted, the investigators stated that the study was conducted in iodine-sufficient areas. The NRC's RfD ($0.7 \mu\text{g kg}^{-1} \text{d}^{-1}$) is likely to be protective of thyroid function in neonates of mothers with adequate iodide intake.

7.14 Developmental Effects of Ammonium Perchlorate

7.14.1 Animal Studies

In a neurobehavioral study of rats, exposure began two weeks before mating and was terminated on PND 10 [1072]. On PND 5, all of the pups were weighed and the litter culled to four males and four females. Tests of motor activity were conducted on one male and one female selected randomly on PND 14, 18, and 22. Nine measures of motor activity were monitored: frequency and time of ambulatory movements, frequency and time of stereotypic movements, frequency of movements in the horizontal plane, distance traveled in the horizontal plane, frequency of rears, total number of horizontal movements made while in rearing position, and time spent resting. Each measure of activity was recorded for 90 consecutive minutes on each test day. Data were divided into nine ten-minute blocks. The results showed that the main effect for perchlorate dose was not significant for any of the nine dependent variables and there were no reliable interactions for treatment. The highest dose tested, $8.5 \text{ mg perchlorate/kg/day}$, is considered a NOAEL for neurodevelopmental effects in this study. A replication of this study [1073–1075] showed that there were no significant alterations in test results due to the consumption of perchlorate relative to controls.

In an evaluation of AP in the endocrine disruptor screening protocol, no changes in delay of puberty in male Wistar rats and no changes in reproductive organ histol-

ogy were observed [1076]. Organ weights were equal to controls at $500 \text{ mg kg}^{-1} \text{ d}^{-1}$ but thyroid and TSH/T4 changes were observed at 62.5 and $125 \text{ mg kg}^{-1} \text{ d}^{-1}$, respectively.

7.14.2 Human Studies

An excellent summary of the developmental effects of perchlorates, both in humans and in animals, is provided in Section 3.2.2.6 (*Developmental Effects*) of the ATSDR study ([1047], pages 69–78).

An evaluation of the potential association between exposure to perchlorate via the drinking water and the incidence of attention-deficit-hyperactivity disorder (ADHD) and autism among children less than 18 years of age who were recipients of Medicaid in Nevada revealed that the rates for ADHD and autism in the area with perchlorate in the drinking water did not exceed the rates in the areas without perchlorate in the drinking water [1077]. Furthermore, there was no difference between the three groups regarding overall fourth-grade school performance. The study included subjects from Clark County, which includes Las Vegas, where the concentration of perchlorate in the public water supply ranged from undetected to $23.8 \mu\text{g/L}$ (mean $10.9 \mu\text{g/L}$), as measured between 1997–2001.

8 Environmental Effects of Ammonium Perchlorate

This book is mainly a book for rocket propellant formulators. However, it is also intended to be a valuable information resource for propellant ingredient production and disposal covering the entire “cradle to grave” life cycle of propellants. For this reason, chapters on toxicity and the environmental effects of perchlorates have been dealt with in substantial detail, amassing several hundred literature references on this topic alone.

When perchlorates were first produced, none of the chemists involved anticipated that it would ever find this widespread distribution and affect drinking water resources in many densely populated areas. The introduction and scaled-up production of new chemicals in the 1950s did not require an environmental review or pre-manufacturing Toxic Substances Control Act (TSCA) notification as it does now. Even now, the environmental impact statements for the continued use of perchlorates leave much to be desired. This was illustrated in a critical review [1078] of the programmatic Environmental Impact Statement prepared by Missile Defense Agency in 2007 for the development, testing, and deployment of a Ballistic Missile Defense System (BMDS). Although the amount of perchlorate anticipated to be used for BMDS is small in comparison to ICBM and Space Shuttle solid rocket booster use, the program has undergone environmental scrutiny [1079–1081].

Perchlorate anion has been found in drinking water supplies throughout the southwestern area of the US where its accidental or negligent releases were primarily

blamed on defense contractors and military operations [1082]. Traces of natural perchlorate are found in Chile saltpeter but the use of such fertilizer has not been associated with large-scale contamination. Many studies involving perchlorate are still underway and many more research papers are being published every month.

In short succession, four significant books on the environmental between the year 2000 and 2009. The four books are:

- [1083] Urbansky (Ed.), *Perchlorate in the environment* (2000)
- [1084] Gu and Coates (Eds.), *Perchlorate: Environmental occurrence, interactions and treatment* (2006)
- [1085] Sellers et al., *Perchlorate: Environmental problems and solutions* (2007)
- [1086] Stroo and Ward (Eds.), *In situ bioremediation of perchlorate in groundwater* (2009)

Combined, these four books constitute a rich and compact source of information on perchlorate pollution. However, in the meantime, the remediation technology continues to make rapid progress. As such, in a few years' time, the books will need to be updated.

The book by Urbansky [1083] is largely based on the proceedings of a symposium held in conjunction with the Fall 1999 American Chemical Society meeting. The book starts with the fundamental chemistry of perchlorate and moves on through other topics. Topics range from toxicology to analytical techniques to treatment and remediation. It contains 25 chapters (derived from papers) organized into three parts. It was the first book published on perchlorate as an environmental contaminant since the discovery of the widespread problem in 1997. Each of these 25 chapters is referenced individually under its appropriate topic at other locations in our book at hand.

A book by Gu and Coates (Eds.) [1084] is a very comprehensive publication with 17 chapters written by individual contributors. It provides a complete review of the environmental effects of perchlorate contamination and offers potential ways to clean up the polluted sites [1087]. The titles of the 17 chapters are:

1. Perchlorate: Challenges and lessons
2. The chemistry of perchlorate in the environment
3. Occurrence and formation of non-anthropogenic perchlorate
4. Alternative causes of widespread, low concentration perchlorate impacts to groundwater
5. Stable isotope composition of chlorine and oxygen in synthetic and natural perchlorate
6. Recent developments in perchlorate detection
7. The ecotoxicology of perchlorate in the environment
8. Perchlorate toxicity and risk assessment
9. Using biomonitoring to assess human exposure to perchlorate
10. Recent advances in ion exchange for perchlorate treatment, recovery, and detection

11. Field demonstration using highly selective regenerable ion exchange and perchlorate destruction technologies for water treatment
12. The microbiology of perchlorate reduction and its bioremediative application
13. The biochemistry and genetics of microbial perchlorate reduction
14. Field demonstration of in situ perchlorate bioremediation in groundwater
15. Perchlorate removal by modified active carbon
16. Titanium catalyzed perchlorate reduction and applications
17. Membrane and other treatment technologies-pros and cons.

Each of these 17 chapters is referenced individually under its appropriate topic at other locations in this publication at hand.

The first two books are just collections (juxtapositions) of chapters (papers) contributed by several authors. A book by a group of authors working with Sellers et al. [1085] is a more homogeneous and coherent exploration of the subject. It is a valuable resource because it contains several case studies and information on the success of several perchlorate pilot-scale and full-scale treatment facilities in the field (as opposed to just laboratory *in-vitro* studies). It also shows photos of several of these installations so the reader can get a feel for the size of the installations (and the expense of building them).

The book by Stroo and Ward (Eds.) [1086] contains 11 chapters, all of which are individually referenced in the current book at hand.

In addition to what was collected in the four books listed above, there is enough information about environmental and public health impacts of perchlorates out there to fill another four books. Besides hard-copy books and essays and reports printed on paper, there are numerous sources on the environmental impact of perchlorates accessible only in electronic form on the internet. Because the URLs of many of these websites are sometimes short-lived, we have abandoned an attempt to list a few representative examples.

In several dozens of many such survey articles, the environmental occurrence, toxicity, analytical chemistry, and remediative approaches are discussed. These publications provide a good introduction into problem areas and some are written in easily understandable terms that even a non-toxicologist can understand [1088–1091].

The EPA has compiled and published a summary of known perchlorate releases in the US. This indicates that perchlorate contamination is a widely spread problem. Maps of the US have been drawn that show the hot spots of perchlorate contamination in the southwestern area of the country. Perchlorate has been detected in fertilizer, milk, lettuce, and many other food products. In an effort to identify the sources of perchlorate and to prevent further spread of the contamination, the EPA has assembled a database of all known perchlorate manufacturers and users in the US. Likewise, the Department of Defense has documented known perchlorate users and has summarized the remedial action taken on behalf of the DoD installations and DoD contractors and has summarized it in a report to Congress [1092]. This is a 31-page table

listing many installations but it lacks an estimate of the quantities of perchlorates that were once manufactured, stored, or disposed at these locations (see [1093] also).

Srinivasan and co-workers [1094] have produced excellent summaries in two publications regarding the health effects of perchlorate and technologies that can be employed for its removal from water sources. The first one contains 107 references, which guide the reader to further in-depth study of this problem. Most of the references are also discussed and are referred to in the book at hand. The first publication was updated and supplemented with a similar review article a few months later [1095]. As of 2011, although some technologies such as microbial reduction and ion-exchange had become more established than others, there was still not a single technology that could be directly applied to a drinking water treatment system for complete removal of perchlorate.

The Department of Defense's Strategic Environmental Research and Development Program (SERDP) and Environmental Security Technology Certification Program (ESTCP) have funded numerous perchlorate remediation and clean-up studies and can serve as a resource for publications on this subject [1096]. As of February 2011, a search for final reports in the SERDP database revealed 299 entries for "perchlorate" and 163 entries for "ammonium perchlorate" along with links to where the reports can be quickly downloaded as .pdf documents.

8.1 Ammonium Perchlorate Distribution and Migration in Aquifers

The release of AP into the environment as a result of accidents or carelessness has caused a significant amount of concern for the health of residents living downstream of the releases as they, of course, depend on pure drinking water for subsistence. Fortunately for the hydrologist studying the migration of contaminant plumes in aquifers, perchlorate ion can now be detected in very low concentrations. Its concentration does not change rapidly by adsorption and chemical or biodegradation during the migration. This makes perchlorate ion a good marker but, unfortunately, it is a very persistent marker.

There are many industrial sites where the perchlorate ion migration in aquifers have been studied after the levels of concern increased in the 1990s [1097]. One of the reports provides detailed data for pollution at the Tronox (formerly Kerr McGee) and AMPAC (referred to as PEPCON in previous reports) plants located in Henderson, NV.

One of the most heavily polluted industrial sites outside the US is a chemical facility in the Ramat Hasharon area in Israel. For 25 years, an AP manufacturing plant disposed of untreated wastewater in four unlined ponds. The research site consisted of the four old infiltration ponds located close to the AP manufacturing plant, about 3 km north of the city of Tel Aviv, Israel. The amount of AP leaked was calculated as ~2400 tons based on the contaminated section of the aquifer, the aquifer thickness, and perchlorate concentrations in the groundwater. The transport mechanisms of perchlorate

infiltrated from 1965 to 1990 from one of these active storage ponds into a deep (40 m) layered vadose zone. As such, the underlying coastal aquifer was measured [1098]. Perchlorate migration from 1990 (when the wastewater disposal ceased) until 2008 (with infiltration due only to natural rain [~ 500 mm/y]) was studied by taking water samples from different depths. Several indirect methods were used, including mass balance in the unsaturated zone profile, concentration profiles below the pond, and a comparison of the same sediment profiles taken in 2005 and 2007. The ^{18}O and ^2H isotopic composition of the pore water could be divided into two separate groups: lighter (depleted) and heavier (enriched) samples. All samples in the lighter group were from the shallow vadose zone, above two clay layers, and represented dilution by natural infiltration of rainwater. The enriched samples were from the deeper section of the unsaturated zone (20–40 m) and represented water used for perchlorate manufacturing 14 years prior to drilling. Consequently, the overall maximum infiltration rate was estimated to be 1.4 m/y. Almost identical perchlorate concentrations were found below the clay layer, along the sediment profile in 2005 and 2007 (two boreholes, 3 m apart). Very different perchlorate profiles were observed above the clay layers. This suggests that perchlorate below the clay layers (20–40 m) is practically stagnant under the current natural conditions. The reduction in perchlorate concentration in groundwater below the ponds versus its increased concentration further downgradient supports the contention that the current migration of perchlorate from the vadose zone to the groundwater is very slow. It was estimated that perchlorate concentration in the groundwater under the infiltration pond, which was 187 mg/L in 2004, will drop to 10 $\mu\text{g/L}$ within about 14 years. The existence of a clay layer crossing the thick vadose zone was found to significantly change the infiltration rate when ponded conditions were replaced with natural precipitation.

A drinking water survey conducted between 1997 and 1998 detected no perchlorate (reporting limit = 4.0 $\mu\text{g/L}$) in the surface water samples from 40 sites in 11 states [1099]. Out of 367 groundwater wells in 17 states which were tested during this survey, only nine wells located in California and New Mexico contained perchlorate. Concentrations in samples from these wells ranged between <4–7 $\mu\text{g/L}$.

Adsorption and release of perchlorate in a variety of soils, minerals, and other media were studied by exposing the solid media to low and high concentrations of perchlorate salts in water [1100]. Low-level ClO_4^- exposure was investigated by subjecting triplicate 5-g portions of a solid medium (38 different soils, minerals, or dusts) to 25 mL of an aqueous AP solution containing 670 ng/mL (6.8 mM) perchlorate. This corresponds to a perchlorate-to-soil ratio of 3.4 mg/g (34 nmol/g/L). At this level of exposure, more than 90% of the perchlorate was recovered in the aqueous phase, as determined by ion chromatography. In some cases, more than 99% of the perchlorate remained in the aqueous phase. The forced perchlorate anion exchange capacities (PAECs) were studied by soaking 5-g portions of the solid media in 250 mL of 0.20-M NaClO_4 followed by repeated deionized water rinses until perchlorate concentrations fell below 20 ng/mL in the rinse solutions. The dried residua were leached with 15 mL

of 0.10-M sodium hydroxide. The leachates were analyzed by using ion chromatography. The perchlorate concentrations found were subsequently used to calculate the PAECs. The measurable PAECs of the insoluble and settleable residua ranged from between 4 to 150 nmol/g, with most in the 20–50 nmol/g range. Overall, the findings support the widely accepted idea that perchlorate does not appreciably sorb to soils and that its mobility and fate are largely influenced by hydrologic and biologic factors. Sorption (anion replacement) of perchlorate appears to occur in some soils. Therefore, the measurement of perchlorate in soils requires accounting for ion exchange phenomena; leaching with water alone may give inaccurate results. If perchlorate anion exchange is confirmed to be negligible, then a sample collection using leaching procedures may be simplified accordingly.

Based on modeling of AP distribution in aquifers, it was predicted that the denser AP/saline brine solutions sink to the bottom of the aquifer where they will remain for a long time and will be a long-term source of perchlorate pollution, even after the primary supply of AP has been stopped. Release from the bottom of the aquifer is mass transfer limited and (in the absence of biodegradation) will have time-scales of approximately 100 years [1101].

Three environmental forensic methods were used as part of an integrated evaluation to determine the extent of dissolved perchlorate in groundwater originating from a former rocket propellant testing site in Southern California [1102]. The methods included the evaluation of groundwater modeling, subsurface environmental conditions, and isotopic fingerprinting. While these methods have been used independently in other environmental forensic studies, this work was the first to document the combined use of these methods to evaluate the extent of dissolved perchlorate in groundwater. Taken together, the results indicated that the perchlorate originating from a former rocket propellant testing site is under hydraulic control and that multiple sources of perchlorate exist within the same hydrogeologic basin.

8.2 Environmental Fate and Biodegradation of Ammonium Perchlorate

Perchlorate anion is not subject to biodegradation as rapidly as nitrate or nitrite anion. It is relatively persistent to both chemical reactions and biodegradation under aerobic conditions. The interest in biodegradation of perchlorate is for several reasons: Hydrologic studies assume that the perchlorate ion in deep aquifers remains unchanged due to biological activity. So, if there is any biological activity affecting perchlorate migration and survival, it has to be quantified. Secondly, it would be very valuable to breed a kind of “superbug” of bacteria that can thrive on perchlorate and be used in bioremediation of contaminated sites and wastewater treatment from industrial processes.

The effects of AP concentration in soil and in water on seed germination, plant growth rate, photosynthesis, microbial respiration, microbial growth, and total biomass have long been studied, well before widespread perchlorate contamination

became apparent [1103]. The select use of bacteria for bioremediation of perchlorate was already patented in 1976, describing the biochemical reduction of perchlorates and chlorates under anaerobic conditions by means of a strain of the micro-organism *Vibrio dechloraticans* Cuznesove B-1168. This is grown by way of successive inoculations on a liquid nutrient medium containing sources of carbon, nitrogen, and phosphorus under anaerobic conditions in the presence of a perchlorate as a donor of oxygen [1104]. It was claimed that such bacteria can reduce perchlorates to chlorides at a rate of 5 g of perchlorate for 3 d per 1 g of the biomass solids and may continue to grow at a concentration of AP as high as 300 mg/L.

A bacterial isolate, strain *perclace*, was shown to reduce the groundwater contaminant perchlorate ClO_4^- to levels <0.005 mg/L when grown on acetate under anaerobic conditions [1105]. The ability of *perclace* to simultaneously reduce perchlorate and another groundwater pollutant, nitrate, NO_3^- , was examined in batch studies and in a sand-packed column under saturated flow conditions. Nitrate removal was monitored using ion chromatography, and perchlorate removal was monitored using a perchlorate ion specific electrode or ion chromatography. In batch studies, the reduction of 0.089, 0.92, 12.0, and 122 mg/L perchlorate was examined in the presence and absence of 62 mg/L NO_3^- . Perchlorate was reduced more rapidly in the absence of NO_3^- than in its presence. However, both perchlorate and NO_3^- were reduced by more than 10-fold within 48 hours. A sand-packed column inoculated with *perclace* simulated a flow-through biotreatment system for water contaminated with a low level of perchlorate and a much higher level of NO_3^- . Biotreatment could reduce perchlorate to <0.005 mg/L in a 3-h residence time. *Perclace* may be used as a substitute for anaerobic bacteria which are otherwise used in biological systems for removing perchlorate and/or nitrate from water or soil [1106].

There has been an intense interest in the environmental fate of spilled perchlorates and there have been several conferences and books devoted entirely to this topic [1107].

When released to the environment, perchlorates are expected to be highly mobile in water-percolated soil and to partition to surface water or groundwater [1090]. They are not expected to significantly adsorb to sediment or suspended organic matter. If airborne, they are also expected to readily settle from the atmosphere by wet and dry deposition. No degradation process for perchlorates in the environment has been unambiguously established. Laboratory experiments suggest that they may be reduced by anaerobic microbes in soil and water, although the presence of sulfates and nitrates in the environment attenuates this process. Laboratory experiments also suggest that perchlorates may undergo uptake by some plants and may be subsequently reduced to chloride. Neither the types of plants that take up perchlorate nor the types capable of reducing it have been well categorized.

Perchlorates have been found to be quite persistent. It was stated that the necessary criteria for perchlorate degradation in soil are anaerobic conditions, an adequate carbon source, and an active perchlorate-degrading microbial population [1108]. Per-

chlorate applied to Yolo loam at 180 mg/L during an anaerobic flooded batch experiment was completely biodegraded after 30 d.

During an analysis of perchlorate-contaminated streambed sediment located near a Naval Weapons Industrial Reserve Plant in McGregor, TX, it was concluded that microbial degradation of perchlorate was taking place based on a sequential depletion of electron acceptors and a constant Cl^- concentration in the sediment [1109]. The level of nitrate found to result in inhibition, 100 mg/L, was on the low end of the range typically found in soils, 0–1200 mg/L. In the absence of nitrate, perchlorate was removed to levels below the detection limit ($<4\text{ }\mu\text{g/L}$) in wetland columns with perchlorate influents of 4, 8, 16, and 32 mg/L [1110, 1111].

The reduction of perchlorate using micro-organisms has been found to be inhibited by the electron acceptors most commonly found in anaerobic environments (nitrate and/or sulfate). In a few cases, they were found to be reduced preferentially. The initial product from the respiration of perchlorate is chlorate (ClO_3^-). This in turn is reduced by some of the bacteria to chlorite (ClO_2^-) and, ultimately, to chloride (Cl^-) and either oxygen or bicarbonate [1112, 1113]. The same bacteria can reduce chlorate as well as perchlorate [1114–1116] (see [1117–1119] also).

8.3 Soil Contamination Case Studies

As of April 2004, the EPA's Office of Solid Waste and Emergency Response and the Federal Facilities Restoration and Reuse department had documented 58 federal sites with known perchlorate releases. These sites included a combination of Air Force, Navy, Army, Department of Energy, and NASA sites. Of these sites, 51 were DoD sites. The office also listed 40 private sites, many of which were owned or operated by military contractors with known releases. Groundwater contamination existed at all of these sites, with perchlorate concentrations as high as 3700 mg/L. Perchlorate in vadose-zone soil existed at many of these sites and can serve as an ongoing source of groundwater contamination. Twenty of the 51 DoD sites were listed as having soil contamination.

The vadose zone is below ground but above groundwater level. It may store spilled contaminants for a long time since it is only purged by precipitation trickling down to the groundwater level. Contaminants in the vadose zone in arid climates are bound to stay there for a long time.

While there has been a lot of publicity about the explosion at PEPCON and the subsequent spill at Henderson, NV, the main source of groundwater pollution is actually another perchlorate plant not far away from the explosion site. Perchlorate production was initiated at the Kerr McGee Chemical Company at other plant locations in 1945, and full commercial production of AP began in 1951 under the prior owners/operators. Kerr McGee acquired the property in 1967 and the company name was changed to Tronox in November 2005.

Perchlorate-contaminated groundwater from the Kerr McGee/Tronox plume flows north, about three miles from Tronox to Las Vegas Wash. Tronox is the most significant source of perchlorate entering Las Vegas Wash; prior to controls being put into place, the Tronox plume released about 900 to 1000 pounds per day (average) of perchlorate-contaminated groundwater to Las Vegas Wash. It was estimated that the plume emanating from the Kerr McGee plant contains 9000 metric tons (20 million pounds) of perchlorate dissolved in 3.4 million m³ (9 billion gallons) of water. The EPA has issued a summary report on the findings of soil and groundwater analyses in the Henderson, NV area [1097].

The former PEPCON/AMPAC perchlorate plant also has a plume of perchlorate but it is smaller and much less concentrated than the Tronox plume. It has been estimated that the plume emanating from the PEPCON plant holds 500 metric tons (1.1 million pounds) of perchlorate in 3.4 million m³ (9 billion gallons) of water. AMPAC conducted an *In-Situ* Bioremediation Pilot Study from December 2002 to April 2003. This effort was successful, reducing perchlorate concentrations from about 500 ppm to less than 2 ppb. During 2003 and 2004, AMPAC conducted additional investigations of the nature and extent of their perchlorate plume.

The environmental pollution situation is slowly improving. Groundwater concentrations are declining as a result of Tronox's capture and control efforts at three locations: a slurry wall on Tronox property, on Athens Road (about halfway to Las Vegas Wash), and a seep area near Las Vegas Wash. Groundwater extraction wells in these three locations are removing approximately 1700 to 2000 pounds of perchlorate per day. Surface water concentrations in Las Vegas Wash, Lake Mead and the Lower Colorado River have declined by 85%, 70%, and 60%, respectively, since seep capture and treatment began in November 1999.

In Israel, widespread perchlorate contamination with peak concentrations of 1200 mg ClO₄⁻/kg sediment has been found in the 40-m deep vadose zone near an AP manufacturing plant that is north of Tel Aviv and above the central part of Israel's coastal aquifer. The perchlorate-reduction potential by native microbial communities along a deep contaminated vadose zone profile was examined [1120]. The effect of various concentrations of nitrate on perchlorate reduction had to be considered because it is possible that perchlorate concentrations in the profile are toxic to the native microbial population. All experiments were performed in soil slurries with sediments taken from the contaminated site. Perchlorate was reduced to chloride in three (1, 15, and 35 m) of the four examined sediment samples taken from different depths (1, 15, 20, and 35 m below surface). No activity was observed in the sediment sample from 20 m below land surface, suggesting low viable microbial communities and water content and high surviving perchlorate concentrations. In the presence of nitrate, the lag time for perchlorate degradation was inversely correlated to nitrate concentration. There was no perchlorate degradation as long as nitrate was present in the system, and perchlorate degradation started only after all the nitrate had been consumed. Nitrate-reduction rates were correlated to the initial

concentrations of nitrate and no lag period was observed for nitrate reduction. Viable microbial populations were observed at both high concentrations (10000 mg/L and 20000 mg/L) and with no addition of perchlorate, at levels of 2.3×10^5 , 4.0×10^5 , and 3.4×10^3 colony forming units (CFU)/mL, respectively. These results were well correlated to those found by polymerase chain reaction (PCR) amplification analysis of chlorite dismutase [1121]. It was suspected that the microbial community has adapted to the conditions of high perchlorate concentrations in the unsaturated zone following 30 years of exposure. That would make them suitable bacteria for the treatment of other contaminated sites. When no external carbon source was added to the slurry of soil from land surfaces, all perchlorate was removed after 134 days of incubation. The average perchlorate-reduction rate using natural organic matter as a carbon source was 0.45 mg/d, while the average rate using acetate as an external carbon source was 7.2 mg/d.

The potential for contamination resulting from discharges at facilities that manufacture and use perchlorate was studied following the accidental fire and subsequent explosion at the PEPCON AP production site in Henderson, Nevada in May 1988 [1122]. Perchlorate concentrations as high as 630000 µg/L were observed in nearby surface water samples following the accident. Nearby groundwater samples were also contaminated with perchlorate at concentrations ranging from 51400 to 630000 µg/L. Monitoring data from 50 wells obtained near the Kerr-McGee AP producing facility, also located in Henderson, NV, had perchlorate levels as high as 3.7 g/L [1122].

Surface water samples taken in August 1997 from the Las Vegas Wash, which feeds into Lake Mead, had perchlorate concentrations of 1500–1680 µg/L [1117].

A mean perchlorate concentration of 450 µg/L was reported in 24 water samples from three sites at the Las Vegas Wash collected in March 2002 near Henderson, NV [1123].

The Los Angeles Metropolitan Water District has detected perchlorate at 8 µg/L at an intake located in Lake Mead [1122]. In a separate study, perchlorate was detected in 57% of 147 surface water samples and 50% of ten pore water samples collected in the Lake Mead area, with average (maximum) concentrations of 10.5 (130) and 19.6 (98.0) mg/kg, respectively [1057]. Reported concentrations of perchlorate in the Colorado River are 5–9 µg/L [1015]. In Utah, perchlorate concentrations in groundwater wells at Alliant Techsystems, a rocket manufacturing site, ranged from 4 to 200 µg/L [1122]. According to a report issued by the EPA in December 2005, surface water concentrations in Las Vegas Wash, Lake Mead, and the Lower Colorado River have declined by 85, 70, and 60%, respectively, since the inception of a seep capture and treatment program at the Kerr-McGee site in Henderson, Nevada, began in November 1999 [1097].

Groundwater samples from a shallow aquifer near the Aerojet General Corporation's solid rocket propellant facility near Sacramento, California, had maximum perchlorate levels of 8000 µg/L [1117].

The frequency of detection of perchlorate and its impacts to soil, groundwater, and surface water (causes that are unrelated to military activities) has increased in the past several years as more and more water utilities have begun to analyze for this constituent as part of their monitoring programs. Based on more detailed product and process information, perchlorate was found to be present (intentionally or unintentionally) in many more products and processes than people were initially aware of. Furthermore, evidence surfaced that perchlorate can be formed naturally in evaporate deposits and through atmospheric mechanisms. The most significant domestic users of perchlorate in North America are the DoD in the US, NASA, and related defense contractors, thus making perchlorate impacts attributable to these groups and facilities. However, cases where perchlorate impacts result from non-military and/or natural inputs need to be included in future studies [1124].

Soil samples from an agricultural field were amended with perchlorate solution and set aside in a shelter exposed to air at the farm for periodic sampling and analysis. The perchlorate content decreased significantly within 20 days, but the cause for the perchlorate degradation was not identified [1125].

8.4 Groundwater Contamination Case Studies

At one point, the state of Nevada Division of Environmental Protection's (NDEP's) website provided a chronological timeline of the events at two perchlorate manufacturing sites near Las Vegas, NV [1126]. That report also provided a map outlining the path of two underground plumes as they migrate toward the Colorado River (Figure 46).

The sources of the perchlorate in Lake Mead were traced upstream to the Las Vegas Wash, which discharges into Lake Mead. Perchlorate was entering the Las Vegas Wash through contaminated groundwater and surface water stemming from a manufacturing facility once owned and operated by Kerr-McGee Chemical LLC (which was renamed to Tronox LLC, as mentioned earlier). Perchlorate-contaminated groundwater was also found to originate from PEPCON, which is owned by AMPAC. The US Navy, Western Electrochemical Company and the American Potash and Chemical Company have owned and operated the current Tronox facility. Perchlorate was produced at this facility from between 1945 until 1998. Perchlorate was manufactured at the AMPAC facility from 1958 to 1988 when an explosion destroyed the PEPCON plant. From 2005 through to 2009, Tronox operated a remediation system that extracted perchlorate-contaminated groundwater for *ex-situ* treatment. This uses a fluidized bed reactor (FBR) treatment system using bioremediation to reduce the perchlorate concentration followed by discharge into the Las Vegas Wash. The discharge water from this remediation system has been consistently less than the Nevada Interim Action Level for perchlorate of 18 µg/L or 18 ppb. AMPAC operated an *in-situ* remediation system where perchlorate-contaminated groundwater was

Figure 46: Migration of perchlorate contaminated groundwater plumes toward Las Vegas Wash and Colorado River. (From NDEP <http://ndep.nv.gov/bca/perchlorate05.htm>.)

extracted and amended with nutrients followed by re-injection into the subsurface near the Las Vegas Wash. This system has achieved the reduction of the perchlorate concentration in the re-injected groundwater from $18\text{ }\mu\text{g/L}$ to non-detectable concentrations of less than 6 ppb by the time it reached the first performance monitoring well. Concentrations in the Las Vegas Wash have decreased by more than 90 percent since 1997. Sampling data from the Willow Beach, AZ, sampling point on the Colorado River (approximately 11 miles downstream from Hoover Dam), revealed a reduction from a high of 9.7 ppb in June 1999 to 1.8 ppb in May 2008. Sampling data from the Northshore Road sampling point in the Las Vegas Wash downstream from Lake Las Vegas revealed a reduction from a high of 1200 ppb in October 1998 to 61 ppb in May 2008. NDEP continued to work with the EPA, Southern Nevada Water Authority, Metropolitan Water District, City of Henderson, Tronox, AMPAC and Black Mountain Industrial complex to develop opportunities to further refine groundwater capture and treatment technologies.

One source of perchlorate contamination of drinking water in Massachusetts in the US was traced to the use of perchloric acid to bleach surgical and medical equipment in an upstream town on the Merrimack River.

In order to obtain a consistent and reproducible set of data on the extent of perchlorate pollution and the effectiveness of clean-up efforts, the DoD has issued a *DoD Perchlorate Handbook* [1127]. Chartered under the leadership of the Department of the Navy, this inter-component task force is responsible for promoting “the generation of environmental data of known and documented quality”. The handbook has the following objectives:

- Ensure cost-effective and consistent approaches across the DoD for sampling and testing activities involving perchlorate;
- Ensure that collected data are of the quality necessary to support decision-making;
- Ensure that information disseminated to the public associated with perchlorate sampling and testing complies with Information Quality Guidelines put forward by the DoD.

The handbook includes guidance for the following areas:

- Use conceptual site models to develop project quality objectives associated with sampling and analysis for perchlorate;
- Design sampling strategies and implementing appropriate sampling techniques;
- Select qualified and certified analytical laboratories and analytical methods based on required performance objectives.

8.5 Seawater Contamination Case Studies

Perchlorates may be released into the environment from booster rockets during a catastrophic failure or aborted flight. Following the Delta II flight failure that occurred at Cape Canaveral in January 1997, it was estimated that 200000 pounds of perchlorate-containing HTPB solid propellant was released [1128].

8.6 Effects of Perchlorate Salts on Plant Growth

It is known that chlorates (predominantly sodium chlorate) have been used extensively as herbicides and that this was one of the possible pathways in which perchlorate (present as contamination in industrial grade sodium chlorate) entered the environment, where it remained for a long time.

Perchlorate itself is less active as an herbicide and not likely to be used for that purpose.

It is known that some plants (e.g., seaweed) have the ability to enrich iodine from seawater [1129]. Likewise, some plants have the ability to enrich perchlorate (perchlorate often mimics the properties of iodide). There is concern that some vegetables in-

tended for human consumption can become enriched in perchlorate if the irrigation water is contaminated with it.

Cucumber (*Cucumis sativus* L.), lettuce (*Lactuca sativa* L.), and soybean (*Glycine max*) were used to determine the uptake of the perchlorate anion (100 ppb) from sand [1130]. Perchlorate concentrations in sand and plant tissues were determined weekly. Perchlorate uptake was observed in all three plant species. In most experiments, perchlorate was completely depleted from sand in which plants were growing. Perchlorate concentrations in lettuce were also significantly higher than those in cucumber and soybean. The results of an eight-week uptake study in cucumber and a six-week uptake study in lettuce suggest that a threshold perchlorate concentration is reached: for cucumber it is 150 ppm, and for lettuce it is 750 ppm.

Notably, during the remediation of perchlorate-contaminated sites, some plants not only absorb perchlorate and enrich it in their tissue, they are also able to reduce it to create a harmless chloride [1131]. Thus, if contaminated sites are revegetated with non-food vegetation, one should select plants that have the ability to reduce perchlorate ion.

Chilean saltpeter, a naturally occurring material proven to contain perchlorates, has been marketed mainly as a granular product for fertilizers. Chilean researchers initiated a study in 1967 to establish why soybeans were exhibiting stunted growth, rugose, and crumpled leaves as a result of domestic fertilizer application and to determine what levels of perchlorate these plants could tolerate [1132]. The saltpeter used to produce the fertilizer at that time contained 0.12–0.26 mass-% perchlorate as a contaminant [1133].

Fertilizer derived from Chilean saltpeter has been traditionally applied mainly to tobacco plants but has also been marketed for citrus fruits, cotton, and some vegetable crops [1133]. The amount of perchlorate present in recent samples of these fertilizers was found to range from 0.7 to 2.0 mg/g. Steps have been taken to reformulate these products to remove perchlorate. Other synthetic fertilizers do not contain perchlorate.

8.7 Aquatic Toxicity of Perchlorates

An *in-vitro* developmental toxicity screen was performed to determine the developmental hazard index (A/D ratio) for AP using the hydra assay. *Hydra attenuata* have the capability for whole body regeneration. Both adult hydra and “artificial embryos” composed of disassociated hydra cells were exposed to AP to investigate developmental toxicity [1134]. Results from the hydra assay of AP indicated that the minimal effective concentrations required to elicit a toxic response in the adult hydra and in the regenerating hydra were 600 mg AP/L and 350 mg AP/L, respectively. The A/D ratio of 1.71 indicated that AP should not be considered a primary developmental toxin in the context of this assay.

Shortly after the perchlorate contamination in aquifers and surface waters were discovered, a battery of screening-level ecological tests were selected based on their availability, rapid turnaround, interpretation power, and susceptibility of organisms [1135]. The test species selected were *Daphnia magna* and *Ceriodaphnia dubia* (free swimming freshwater aquatic invertebrates commonly called water fleas), *Pimephales promelas* (fathead minnow), *Eisenia foetida* (the redworm), and *Lactuca sativa* (a leaf lettuce). An ecological risk assessment was then conducted incorporating a toxicity evaluation, exposure analysis, and risk characterization. Effects, measured as growth and mortality, ranged from a no observed effect concentration (NOEC) of 10 mg/L in *Ceriodaphnia dubia* to a NOEC of 155 mg/L in *Pimephales promelas*. The range of LC₅₀s was 66 mg/L in *Ceriodaphnia dubia* to 4450 mg/L in *Eisenia foetida*.

Limited data indicate that perchlorate may accumulate in living organisms as it has been detected in vegetation, fish, amphibian, insect, and rodent samples collected near known contaminated sites [1136]. Microbial (algal and bacterial) and fish tissues bio-accumulated ClO₄⁻ to high levels and to the magnitude of ClO₄⁻ accumulation corresponded well to exposure levels. The concentrations of ClO₄⁻ in three male spine stickleback fish (*Gasterosteus aculeatus*) were 0.63, 0.54, and 4.47 µg/g, corresponding to aquarium water perchlorate concentrations of 0, 1, and 10 ppm, respectively [1137]. The presence of potassium perchlorate at concentrations up to 10 ppm and ClO₄⁻ concentrations nearing 30 ppm in aquaria containing solid propellant had no effect on stickleback mating or the birth and growth of fry. Fry mortality occurred in all treatments but none were statistically different from controls.

Eggs and larvae of *Xenopus laevis* were exposed to varying concentrations of AP or a control medium for 70 days [1138–1140]. Most treatment-related mortality was observed within five days after exposure and was due in large part to reduced hatching success. The five- and 70-days median lethal concentrations (LC₅₀s) were 510 ± 36 mg AP/L and 223 ± 13 mg AP/L, respectively. AP did not cause any concentration-related developmental abnormalities at concentrations below the 70-day LC₅₀. Although AP was not teratogenic, concentrations reported in contaminated surface waters did inhibit metamorphosis. AP inhibited metamorphosis in a concentration-dependent manner, as evident from effects on forelimb emergence, tail resorption, and hind limb growth. It can be concluded that AP pollution may pose a threat to normal development and growth in amphibian populations.

Thirteen reports that examine the ecological risk of AP on aquatic animal life were summarized in [1141]. The reports deal with the uptake and elimination of perchlorate in American bullfrog larvae, the effects of AP-contaminated and reference surface waters on metamorphosis in *Xenopus Laevis*, and the lethal concentration determination of sodium perchlorate on *Xenopus Laevis*, fish, and amphibians as aquatic sentinels for perchlorate exposures. They also report on *in-situ* exposure of fish and amphibians to perchlorate.

Adult zebrafish were reared up to eight weeks in control water or in water containing AP at measured perchlorate concentrations of 18 ppm (environmentally relevant, high) or 677 ppm [1142]. At 677 ppm, spawn volume was reduced within one week and became negligible after four weeks. At 18 ppm, spawn volume was unaffected even after eight weeks. An eight-week exposure of adult zebrafish to 18 ppm perchlorate affected the histological condition of their thyroid follicles but not their reproductive performance. The effect of 677 ppm perchlorate on reproduction may be due to extrathyroidal toxicity.

The kidney is also a potential target of the direct (association with iodide transporters) or indirect (decreased thyroid hormones and increased TSH) actions of perchlorate. To study the histopathological effects of AP on zebrafish kidneys, adult zebrafish were exposed to water-borne perchlorate at concentrations of 18 ppm for eight weeks and 677 ppm for four weeks [1143]. At the end of the exposure period, the fish were processed for histological analyses of the trunk region of the kidney. The results indicated that exposure to AP at 18 ppm for eight weeks caused a significant increase in the incidence of renal macrophage aggregates when compared with the control fish. The other lesions showed no changes in incidence at any AP dose. The study also suggests a link between thyroid disruption and increases in renal macrophage aggregates.

Fillets and heads of fish collected from Lake Waco and Lake Belton in Texas (located near the Naval Weapons Industrial Reserve Plant where solid rocket motors are manufactured) were analyzed for perchlorates [1144]. Perchlorate concentrations in positive samples ranged from 146 to 2740 µg/kg wet weight in fillets and from 626 to 4560 µg/kg wet weight in heads. Possible routes of exposure for these fish include the ingestion of contaminated periphyton (algae film), contaminated detritus, and the ingestion of perchlorate-containing invertebrates.

The long-term effects of perchlorate on developing amphibians (e.g., growth, metamorphosis) and on the general health and reproductive capacity of adult females were studied *in-vitro* [1145]. The studies examined the effects of perchlorate present in the water as well as perchlorate available through the food chain. Because perchlorate competes for iodine binding sites in the thyroid, the addition of iodine to culture water was examined to determine if perchlorate effects can be mitigated. Perchlorate was found to affect the normal pigmentation of amphibian embryos, however, so does UV irradiation.

Mosquitofish (*Gambusia holbrooki*) adults and fry were exposed to aqueous sodium perchlorate at 1, 10, and 100 mg/L, and growth and reproductive performance were determined [1146]. Five-day acute toxicity tests were also performed. The LC₅₀ of sodium perchlorate was 404 mg/L. Growth was enhanced at 1 mg/L but inhibited at 10 mg/L. These results suggest that, at environmentally relevant concentrations, perchlorate does not induce acutely toxic effects but may have mild stimulatory effects on fitness parameters in this species. In another study, the same type of fish were exposed to 0.1–1000 mg/L NaClO₄ for 12 hours and one, two, five, ten, and 30 days, and perchlorate was determined in whole body extracts [1147]. Perchlorate

was not detected in fish exposed to the low concentrations of perchlorate (0, 0.1, and 1 mg/L), regardless of the exposure time, whereas it was detected when fish were exposed to 10, 100, and 1000 mg/L. The tissue concentrations were approximately ten times less than that in the water (see [939, 1148]).

From AMPAC MSDS (no specific sources of these data were listed):

- *Daphnia Magna* Acute 48-hour LC₅₀ 490 mg/L water with sodium perchlorate
- *Pimephales promelas* Acute 96-hour LC₅₀ 1655 mg/L water with sodium perchlorate
- *Ceriodaphnia dubia* Chronic six-day LC₅₀ 77.8 mg/L water with AP
- *Pimephales promelas* Sub-Chronic six-day LC₅₀ 270 mg/L water with AP
- *Eisenia fetida* Acute seven-day LC₅₀ 4450 mg/kg soil

The toxicity of sodium perchlorate to earth worms *Eisenia fetida* was evaluated in sub-chronic tests in artificial soil. The sub-chronic (21-day sand tests) EC₅₀ for sodium perchlorate to *E. fetida* reproduction (cocoon production) was 1.3 µg/g. The sub-chronic (28-day artificial soil tests) EC₅₀ for sodium perchlorate to *E. fetida* reproduction (cocoon production) was 350 µg/g [1149].

8.8 Toxicity of Perchlorates to Wildlife

Animals living on or near perchlorate-contaminated sites may ingest perchlorate with their forage and scatter it with their excrements.

Raccoons were chosen to evaluate perchlorate exposure and AP effects on large mammals inhabiting the contaminated Longhorn Army Ammunition Plant (LHAAP) located in East Texas [1150]. Many locations on the site were directly involved with perchlorate handling, maintenance, and detonation. Soil and water samples collected on the site had perchlorate concentrations up to 1030 ppm [1136]. Potential forage items had varying levels of perchlorate concentrations of up to 5557 ppm (crabgrass). Concentrations of perchlorate in amphibians ranged from below detectable levels to 2.5 ppm in tadpoles. The decision to study raccoons was based on the types of food a raccoon consumes. Blood samples were collected from trapped raccoons. Samples were analyzed for perchlorate residues and thyroid hormone concentrations. Fifty plasma samples were analyzed for perchlorate residue but they were all below the detection limit of perchlorate in plasma (~100 ppb) except for one animal which had a trace of perchlorate in its plasma. Results from this study did not detect any appreciable perchlorate exposure among raccoons at the LHAAP or resulting effects on thyroid function. If perchlorate exposure had resulted in thyroid changes among raccoons, one would expect to see a negative correlation between T3, T4, and TSH. For example, TSH levels would be high while corresponding T3 and T4 levels would be low. One lonely raccoon with trace amounts of perchlorate present in his blood

plasma had lower concentrations of T3 and T4 and higher concentrations of TSH in relation to the rest of the captured population, in line with expected changes.

Preliminary data from experiments in which pairs of deer mice (*Peromyscus maniculatus*) were exposed to 0, 1 nM, 1 μ M, and 1 mM AP (0, 1.59×10^{-5} , 1.60×10^{-2} , and $15.78 \text{ mg kg}^{-1} \text{ d}^{-1}$ perchlorate ion; ten pairs per dose group) in drinking water suggested that AP adversely affected growth (i.e., a decrease in pup body weights at the highest dose), and development (i.e., differences in kidney, liver, and heart weights in pups) [1151, 1152]. However, there was much scatter in the data. Subsequent studies using the same dose groups extended the exposure time to the weaning of the third litter. Reproductive and growth parameters in the second litter pups at PND 21 revealed a dose-related decrease in litter size, however, this decrease was not significant at any dose level. Additionally, there were no significant differences in body or organ weights when the data was analyzed using individual litters as experimental units. The only statistically significant dose-related effect was in the 1 μ M and 1 mM dose groups with a decrease in heart weights in male pups on PND 21.

The most comprehensive summary of the effects of perchlorate releases on wildlife is a 66-page report by the US Army Center for Health Promotion and Preventive Medicine. This provides a thorough literature survey of published data (including items published through 2006) which includes a wide range of wildlife species, including mammals, birds, and amphibians. It also provides data for laboratory animals exposed to perchlorates [940].

8.9 Remediation of Ammonium Perchlorate Pollution

Once perchlorate ion enters the environment, it is very difficult to reverse its spreading to adjacent surface water bodies and aquifers. Conventional water treatment technologies, including aerobic biodegradation are not efficient at removing perchlorate from water. As of 2009, the DoD in the US had spent over 114 M\$ (megadollars = million dollars) on research regarding perchlorate treatment, substitutes, and detection methodologies. This is in addition to substantial funds spent by other government agencies, local administrations, and water districts. The rate of degradation under the effect of natural influences is very slow (see Section 8.2). Methods are sought which will accelerate natural degradation processes, either in retaining ponds or in natural environments. In selecting remediation technologies, one must differentiate between *in-situ* and *ex-situ* remediation methods. If possible, one will attempt to eliminate the problem at the source (*in-situ*). Any of the *ex-situ* methods would require that the contaminated media (soil, water) be moved to a treatment site.

The Interstate Technology and Regulatory Council (ITRC, <http://www.itrcweb.org/home>), a coalition of state environmental regulators working with federal partners, industry, and stakeholders to advance innovative environmental decision making, has formed a working group on perchlorate remediation. The ITRC Perchlorate Team

reviews new and/or innovative perchlorate remediation technologies to determine the availability and effectiveness of these technologies to reduce concentrations of perchlorate in groundwater and/or soils. A pair of two excellent summary reports on remediation technologies was issued in 2005 [1153, 1154]. Appendix A in the latter report contains a detailed narrative of case studies of perchlorate contamination and remediation. The federal US, as well as the California State Environmental Protection Agencies, have published lists of available, tested, and untested treatment technologies [1155, 1156], including lists of planned and operational water treatment installations (see [1157]).

There currently are two major above-ground technologies used to treat large volumes of water that contain perchlorate: ion exchange and biological treatment. Other technologies under evaluation include membrane filtration and electrodialysis.

A very detailed report summarizing various treatment technology options and compiling a list of clean-up projects in progress in the US was compiled by Ground-Water Remediation Technologies Analysis Center (GWRTAC) in Pittsburgh, PA [1158].

The NDEP along with the SNWA, the EPA, the City of Henderson, and Kerr-McGee began to investigate the source of the perchlorate. When the sources of perchlorate had been identified, remediation plans were enacted to remove perchlorate from groundwater and surface water. The perchlorate flow rate entering the Las Vegas Wash has been reduced by approximately 90% since 1997. As of August 2008, approximately 2638 tons of perchlorate had been removed from the environment. NDEP continues to monitor perchlorate levels reported in the Lower Colorado River, which is below the safety limit set by the EPA in February 2005.

The California-based Department of Toxic Substances Control, which forms part of the EPA, and the Office of Pollution Prevention and Technology Development has compiled a list of perchlorate contamination treatment alternatives [1159], including a nine-page detailed table where various technologies are compared and evaluated.

The Hazardous Waste Clean-Up Information (CLU-IN) website (<http://www.clu-in.org/>) provides information about innovative treatment and site characterization technologies to the hazardous waste remediation community for perchlorate and other pollutants. It describes programs, organizations, publications, and other tools for federal and state personnel, consulting engineers, technology developers and vendors, remediation contractors, researchers, community groups, and individual citizens. The site was developed by the EPA but is intended as a forum for all waste remediation organizations.

In the meantime, the problem of perchlorate contamination in groundwater has spread to other spacefaring nations and improved methods are sought for wastewater remediation [1160]. It has also been recognized that there are natural sources of perchlorate in some groundwaters.

Previously, prior to perchlorate pollution problems becoming known, groundwater pollution due to nitrate had been a persistent concern, particularly so in agricultural communities. This was due to runoff from fertilized fields seeping into

the groundwater and drinking water supply wells. It now appears that the new water treatment technologies stimulated by the need of perchlorate removal from drinking water can be beneficially used for the removal of nitrate from drinking water as well.

8.9.1 AP Removal by Using Ion Exchange

Perchlorate removal from groundwater via ion exchange has been commercially accepted by the water treatment industry and is now being used in dozens of installations across the US. Ion exchange technology uses an anion exchange resin loaded with chloride ion to absorb perchlorate and remove it from drinking water. The contaminated water is pumped through columns containing resin beds, which are two to six feet in diameter and one to six feet high, releasing harmless chloride in its place and affording the opportunity for safe and appropriate disposal. The most promising physical removal process for treating perchlorate-contaminated water uses ion exchange technology. Commercially available ion exchange resins such as Purolite® and Amberlite® resins have been tested for perchlorate sorption. Perchlorate can be removed from water using ion exchange columns. The exhausted resin is regenerated using sodium chloride. The perchlorate brine, containing 7–12% perchlorate, is disposed of in accordance with local regulations.

A study was conducted to evaluate the performance of a small-scale ion exchange unit for the removal of nitrate and perchlorate from groundwater at Lawrence Livermore National Laboratory's Site 300 [1161]. The unit contained 2.5 cu. ft. of Sybron SR-7 resin and was able to treat 3600 gallons of groundwater at an average influent concentration of 100 mg/LNO₃⁻ before breakthrough occurred. Seventy gallons of regeneration waste was generated in the process. The effluent concentration was about 20 mg/LNO₃⁻, which is equivalent to a treatment efficiency of at least 80%. There were several options for implementing this technology: A target well had a 3 to 4 gpm flow rate and concentrations of 90 mg/LNO₃⁻ and 40 µg/L perchlorates. The different treatment options included ion exchange treatment of nitrate only, both nitrate and perchlorate, or perchlorate only. If only perchlorate is to be removed with selective ion exchange resins, a 55-gallon canister filled with ion exchange resin should be able to reduce perchlorate concentrations in the groundwater from 40 µg/L to non-detect levels. The contaminant-laden resin would be disposed of as hazardous waste. It is not practical to regenerate this resin because of the difficulty of removing perchlorate from the resin. Due to the selectivity of the ion exchange resin, it is possible to selectively remove perchlorate from nitrate-contaminated water.

In 2003, Kerr McGee (now Tronox, as mentioned previously) constructed a new FBR, biologically based perchlorate treatment plant to replace the existing ion exchange units at Henderson, NV. The Plant Ion Exchange Units (12) began operating in October 2002 while the Wash Ion Exchange Units (3) began operating in November 1999. The new FBR plant was in startup/shakedown mode from December 2003 through September 2004 and became fully operational in November 2004. The per-

chlorate concentration and mass discharged from the new treatment plant have decreased to less than 18 ppb and less than 0.21 pounds per day, respectively, based on a flow of 1000 gallons per minute. The Plant Ion Exchange Units have not operated since March 2004; the Wash Ion Exchange Units have not operated since June 2004. All ion exchange units were decommissioned by Tronox during the fall of 2005 but the units still remain on site. If one looks at the cumulative amount of perchlorate removed by these units, one arrives at astoundingly large numbers. It seems that there is enough perchlorate in the ground under these former production sites to make it worthwhile to mine it as a mineral resource.

There are two types of ion exchange methods for perchlorate removal: (1) a selective but non-regenerable PS anion exchange resin or (2) a polyacrylic non-selective anion exchange resin with NaCl brine regeneration (described by Gu and Brown in Chapter 10 of [1160]). In the first case, the spent resin cannot be regenerated. As such, it has to be discarded, which is not cost-effective. In the second case, the regenerable resins have poor selectivity and absorb all other anions other than chloride. For instance, the doubly negative charged sulfate ion is more strongly adsorbed than the singly charged perchlorate ion. Non-selective ion exchange resins can be regenerated but they require frequent treatment because they are quickly exhausted by adsorbing other ions beyond the one of interest. Newly developed highly selective ion exchange resins include Amberlite PWA-2 and Purolite A530E, which promise to reduce secondary waste generation and reduce both capital and operating costs of perchlorate removal [1162].

Two demonstration projects in California used a highly selective bifunctional resin for ClO_4^- sorption and a FeCl_3 -HCl solution for the regeneration of the resin [1163].

Selective ion exchange using bifunctional synthetic resins is one of the most effective treatment technologies for removing low levels of perchlorate from contaminated water because of its high efficiency without adverse impacts on the water quality caused by adding or removing any chemicals or nutrients. A bifunctional resin, D-3696, was found to be highly selective toward ClO_4^- and performed much better than one of the best commercial nitrate-selective resins (Purolite A-520E) and more than an order of magnitude better than the Purolite A-500 resin (with a relatively low selectivity) [1164]. At an influent concentration of $\sim 450 \mu\text{g/LClO}_4^-$ in groundwater, the bifunctional resin bed treated ~ 40000 empty bed volumes (BVs) of groundwater before a significant breakthrough of ClO_4^- occurred. Regeneration of the resins after groundwater treatment was also evaluated using the FeCl_3 -HCl regeneration technique.

Treatment of perchlorate-contaminated water using highly selective regenerable ion-exchange and perchlorate-destruction technologies was demonstrated at a field site in California [1165]. Four treatment and four regeneration cycles were carried out and no significant deterioration of resin performance was noted during the two-year operating time. The bifunctional resin (Purolite A-530E) treated about 37000 empty BVs of groundwater before a noticeable breakthrough of perchlorate occurred at an

average flow rate of 150 gpm (or 1 BV/min) and a perchlorate concentration in the feed of about 860 $\mu\text{g/L}$. Sorbed perchlorate was quantitatively recovered by eluting with as little as 1 BV of the $\text{FeCl}_3\text{-HCl}$ regenerant solution. The eluted ClO_4^- was highly concentrated in the third quarter of the first BV of the regenerant solution, with a concentration up to 100000 mg/L. This concentrated effluent greatly facilitated subsequent perchlorate destruction or recovery by precipitation as KClO_4 .

Instead of eluting the adsorbed perchlorate and generating another waste stream, the perchlorate that is adsorbed on the ion exchange resin can be reduced while it is immobilized by a recirculating stream of a strong reductant such as a titanium(III) solution. The Ti(IV) is then reduced back to Ti(III) electrochemically and returned to the ion exchange column in a closed loop [1166]. In 2005, Siemens Water Technology installed a dual 12-foot diameter ion exchange system on a treatment well downgradient of a former landfill in the City of Rialto, CA [1167]. The Siemens solution features throw-away, single-use ion exchange technology. These throw-away resins are highly selective for perchlorate. Complete destruction of the perchlorate ion can be accomplished through the incineration of the spent resin.

Ion exchange is not a disposal technique. It is only a separation technology that transfers the perchlorate from contaminated waters to the waste solutions used to regenerate the resins. Therefore, the perchlorate problem is only really moved from one location to another. The question is what should be done with the perchlorate-rich effluent when the ion-exchange resins are regenerated. The waste solutions ("brine") contain high perchlorate concentrations and treatment technologies for these regenerant solutions are needed. It was proposed to combine ion-exchange (for perchlorate removal and concentration) and biological reduction (effective perchlorate destruction) for treating the waste solutions resulting from resin regeneration [1168].

A biological process for perchlorate and nitrate destruction in concentrated brine from ion exchange processes demonstrated that the salt-tolerant anaerobic culture consistently reduced perchlorate and nitrate in spent brine to below detection limits within 24 hours in the presence of varying concentrations of brine constituents such as salt (3 to 10% NaCl), nitrate (400 to 4000 mg/L), sulfate (600 to 6000 mg/L) and pH (5 to 9) [1169].

The removal of perchlorate and nitrate from contaminated drinking water using regenerable ion-exchange processes produces a high salt brine (3–10% NaCl) laden with high concentrations of perchlorate and nitrate. A bench-scale experiment evaluated the operation of acetate-fed granular-activated carbon (GAC) based FBR for perchlorate-only and also for combined nitrate and perchlorate removal from synthetic brine (6% NaCl) [1170]. The GAC was inoculated with a salt-tolerant culture used previously in batch systems. The FBR was an effective design for perchlorate reduction and exhibited first-order degradation kinetics with respect to perchlorate concentrations. Nitrate was also removed by the organisms in the column and had no negative effects on the removal of perchlorate.

Single-use ion-exchange resins can be regenerated in biological batch systems. Experimental studies demonstrated that perchlorate exhausted resin was effectively regenerated by a salt-tolerant perchlorate-reducing culture [1171]. A mathematical model was developed that incorporates physical desorption and biodegradation parameters and was confirmed by experimental data.

Apparently, the ion exchange plant installed by the Calgon Carbon Corporation (now Kuraray) at La Puente, San Gabriel Valley, CA is one of the largest drinking water purification plants in the world. A similar installation is demonstrated in Figure 47.

Figure 47: Perchlorate removal by using ion exchange. (Photo courtesy of Calgon Carbon Corporation – Kuraray; Reproduced with permission.)

Another full-scale installation using non-regenerable ion exchange installed by Calgon Carbon Corporation is demonstrated in Figure 48.

In an effort to identify ion exchange resins with the best selectivity for perchlorate, 17 different commercially available anion exchange resins were tested and characterized by their matrix, functional group, percent crosslinking, and porosity [1172]. The three matrices were PS, polyacrylic amide, and polyvinylpyridine. The most common quaternary amine functional group is trimethyl(polyalkyl)ammonium but four others were also evaluated. More hydrophobic resins had higher separation factors. The highest separation factors were for resins with triethyl and tripropyl ammonium functional groups, but only at the expense of very slow equilibrium attainment.

The affinity between perchlorate ions and resins is extremely high, which makes it difficult to regenerate resins and results in large amounts of brine that need to be disposed of otherwise. Several BVs of 12% NaCl solution can remove only a small frac-

tion of the perchlorate loaded onto PS-type resins. Heating during regeneration did not lead to much improvement. Acrylic-type resins are easier to regenerate [1173]. In some cases, it is more economical to discard the resins after they are exhausted instead of trying to regenerate them. In the ion exchange process, not only is the affinity of the single perchlorate ion important but the affinities of all other competing ions in the untreated water is of equal importance because they will compete with perchlorate for resin sites. It was noted that the selectivity coefficient of some quaternary ammonium resins increased and almost tripled as the perchlorate loading increased. This behavior prompted speculation that the ions may form ion pairs in concentrated aqueous solutions. The formation of dimerized perchlorate ions $(\text{ClO}_4)_2^{2-}$ has not been experimentally proven; it is just a theory at this point [1174]. The best resin for treating perchlorate-contaminated water is a hydrophobic resin. A hydrophobic resin was able to adsorb the most perchlorate per cycle and was easier to regenerate.

Bifunctional anion exchange resins carry two types of quaternary ammonium groups: the first has long alkyl chains for higher selectivity and the second has shorter alkyl chains for improved reaction kinetics [1175]. They were selected based on systematic experiments where the length of the alkyl chains on the quaternary ammonium groups was varied and its effect on the selectivity was measured. Results indicate that the bifunctional resins performed ~5 times better than the best monofunctional resin (e.g., Purolite® A520E) tested up to that time.

The Calgon Carbon Corporation has designed an ion exchange system that generates substantially less waste brine because the perchlorate-loaded brine from the resin regeneration effluent is passed through a catalytic reactor where nitrate and perchlorate are reduced to nitrogen and chloride using ethanol as a reductant [1176]. The system involves sequential segmentation of the mass transfer zone where the loaded segment of the resin is continuously removed from the top of the mass transfer zone and the regenerated resin is returned to the bottom of the mass transfer zone. This leads to better utilization of the ion exchange resin during the adsorption cycle. Pilot testing of several units was conducted at two different field sites for a total period exceeding six months, generating treated water that met all DWSs.

As it turns out, ion exchange resins that were developed specifically for the removal of radioactive pertechnetate ion from contaminated groundwater in nuclear reprocessing plants are equally effective in the removal of perchlorate [1177]. It was found that selectivity for large and poorly hydrated ions (like perchlorate) can be improved by increasing the size of the organic resin-bound cation. It was determined that a large-sized cation on the resin improved selectivity for perchlorate binding when combined with a less polar binding site. When strong-binding PS resins were used, it was not possible to regenerate them with brine solution (the most common regeneration method for ion exchange resins). Tetrachloroferrate was found to be successful in regenerating PS resins [1165]. Acrylic type resins, on the other hand, have a higher perchlorate capacity as well as a better regeneration efficiency [1173], however, they have low perchlorate selectivity and prefer sulfate over perchlorate and nitrate. Sulfate is a frequent companion in groundwater and would tie up active sites that were intended for perchlorate.

Perchlorate selectivity, capacity, and the thermodynamic properties of resins using commercially available ion exchange resins were measured and computer models using equilibrium multi-component chromatography theory were developed and compared to experimental results [1178]. Three treatment approaches emerged as viable options for reducing perchlorate concentrations to below proposed maximum permissible limits: **(1)** partial exhaustion-regeneration using polyacrylic resins, with a process similar to current nitrate treatment techniques, **(2)** partial exhaustion-regeneration using PS resins with elevated temperature regeneration, and **(3)** use of highly perchlorate-selective resins with resin replacement following exhaustion.

New regenerable resins based on additional Lewis acid/base forces between the ligands and the ions were developed specifically for perchlorate removal from contaminated water [1179]. For this resin, sorption kinetics improved and regeneration was pH-dependent. This resin, however, included bound copper ions which were found to leach out of the resin under unfavorable conditions. A standard strong-base anion and a weak-base anion exchange resin, a bifunctional resin (A-530E), a class of polymeric ligand exchangers and ion-exchange fibers were compared with respect to perchlorate sorption capacity, kinetics, and regenerability [1180]. While A-530E offered the greatest perchlorate capacity and selectivity, practically acceptable capacity was also

observed for the other candidates. The bifunctional resin (A-530E) was least regenerable. In contrast, polyacrylic resins offered much lower perchlorate capacity. The greater capacity of styrenic resins was attributed to enhanced ion-pairing and Lewis acid-base interaction due to the hydrophobic nature of PS matrices and lower hydration energy of perchlorate. Another ion exchange demonstration project was started at Edwards Air Force Base in California [1181].

8.9.1.1 Tradeoff: Regenerable Versus Non-Regenerable Ion Exchange Resins

There are three primary types of perchlorate-removal treatment systems:

- Non-regenerable fixed bed
- Regenerable (ISEP[®]) moving bed
- Regenerable fixed bed (not yet in commercial use).

Non-regenerable systems offer the advantages of simplicity. They can be installed quickly: Modular systems enable complete package delivery of vessels, piping, instrumentation, and resin with six weeks. Systems can be running within a week after delivery – they only need to be set on a level surface, such as a concrete pad or railroad ties. They also have few moving parts, require less operator intervention and expertise, and provide the convenience of resin replacement (by the supplier), rather than regeneration. The disposable anion exchange resins used in non-regenerable systems have a much higher selectivity for perchlorate than regenerable resins. Because these resins continue to remove perchlorate long after all other anionic species have reached breakthrough, they can be online for weeks or months before they are saturated. After a complete breakthrough of perchlorate is detected, the spent resin is removed from the system and incinerated. Fresh resin is filled to replace the spent resin. Resin incineration, with certificates of destruction, allows absolute mitigation. There is no concern about the disposal of regeneration brines like those that carry away the perchlorate from regenerable resins [1182].

Regenerable moving bed systems are favored at higher flow rates (due to economics) and when the water has a high ionic load (due to other pollutants – nitrates, sulfates, and some bicarbonate – that also need to be removed).

Calgon Carbon's ISEP[®] regenerable moving bed system uses a more easily regenerable acrylic resin with a brine regeneration (a standard sodium chloride solution similar to that used in a home water softener system). The technology has the advantage of maximizing the performance of the system through reduced regenerate usage, reduced resin requirement, and steady-state operation. As of 2002, 3.6 mgd of groundwater were treated with ISEP[®] technology, with more than 21.6 mgd of the additional capacity expected to come online in the following year. The operating system at La Puente Valley County Water District in California has been operating at less than 4 ppb perchlorate; treated water samples at Calgon's analytical lab were registering less than 2.5 ppb. Regenerable moving bed systems have more moving parts and the resins require regeneration after a matter of hours online. Nonetheless, by minimizing

the volume of waste brine and the amount of regenerate needed, the ISEP[®] technology delivers lower operating expenses than a non-regenerable system.

Regenerable fixed-bed (FXB) systems use the same ion exchange technology as regenerable ISEP[®] systems. However, current operating costs are higher due to lower brine regeneration efficiencies and higher waste volumes. The FXB technology has yet to be proven.

Another approach to remove perchlorate from water is to use a dendritic anion host. Dendrimers are repeatedly branched, roughly spherical large molecules, and can carry perchlorate-binding functional groups at the tips of the hydrocarbon chains. Dendrimers are typically symmetric around the core and often adopt a spherical three-dimensional morphology. It was suggested that dendrimers can improve the selectivity of perchlorate uptake in the presence of sulfate [1183]. It was also hypothesized that the capacity of these resins is larger, thus improving regeneration as well. Large dendrimers are still rather expensive.

Dendrigrraft ion exchange resins have binding sites throughout the volume of the resin particle (not only on the surface) resulting in large capacity. Branched dendrigrrafts with perchlorate binding sites were synthesized [1184]. Crosslinking was performed with poly(ethylene glycol) (PEG) to strengthen the resin and reduce biofouling. This technology is expected to be implemented as a fixed bed system with NaCl regeneration. Both uncrosslinked, water-soluble dendrigrrafts and PEG-crosslinked, water insoluble dendrigrrafts were investigated. Resins were tested in the presence of high perchlorate concentrations to ensure that even in the presence of high nitrate and sulfate concentrations, the capacity for perchlorate would still be high. The highest perchlorate capacities, up to 325 meq/g, were found in the soluble dendrigrrafts. These dendrigrrafts are regenerable with a lower concentration brine. It was found that dendrigrrafts are an effective way to produce high perchlorate capacity and regenerable resins with good selectivity towards perchlorate.

8.9.2 AP Removal by Using Bioremediation

Biological treatment (also known as bioremediation) is a micro-biological process that uses micro-organisms to break down perchlorate into other components. The underlying science is biodegradation, which looks at processes in natural environments. Human-engineered biodegradation applied to a specific contamination problem is often called *bioremediation*. This involves trying to accelerate and control naturally occurring processes and actively monitor their outcome. In this process, water is treated in a tank (*ex-situ*) using micro-organisms that thrive on perchlorate, or in the ground (*in-situ*) using native organisms or bacteria bred to maximize perchlorate conversion. The current section describes fundamental studies applicable to either method, and more detailed sections dealing specifically with *ex-situ* and *in-situ* treatments will follow. Small amounts of carbon sources, such as alcohol, glycerin or corn syrup, are also placed in the water as nutrients. The micro-organisms then convert the perchlorate

and carbon into two primary components: Carbon dioxide and chloride. The bacteria reduce perchlorate to chlorate and chlorite [1185]. The chlorite subsequently disproportionates into chloride and oxygen under the influence of chlorite dismutase [1121].

Perchlorate-reducing anaerobic heterotrophic bacteria were first identified in the 1960s as a byproduct of the search for nitrate-reducing bacteria. The results remained a scientific curiosity for 30 years until clean-up of the widespread perchlorate pollution in the US began and when other parts of the world required clean-up techniques that would require less chemicals and less energy. The process was initially developed for industrial wastewaters with relatively high perchlorate concentrations in stationary treatment reactors [1104]. However, it was later extended to less concentrated aqueous solutions and *in-situ* underground treatments.

Biological reactors have been used in Europe with good results for the removal of nitrate from drinking water using ethanol or hydrogen gas as the electron donor. Other bioreactors have used acetate as the electron donor. Different types of bioreactors, such as completely mixed stirred constant flow reactors, plug flow reactors (PFR), FBRs, and rotating biological reactors (RBC) were modeled and optimized for perchlorate bioremediation [1186]. In many fixed-film reactors, the biofilm is attached to a substrate (e.g., sand, granulated activated carbon).

The presence of large amounts of nitrate will prevent the reduction of perchlorate because bacteria like to feast on both (nitrate and perchlorate) and compete for the electron donor. However, it was demonstrated that in an enrichment culture from municipal anaerobic digester sludge (ADS) (perchlorate digestion is not mediated by nitrate reductase, but rather by its own reductase enzyme. A mixed bacterial culture capable of reducing perchlorate stoichiometrically to chloride under anaerobic conditions was enriched using municipal digester sludge. The reduction of 10 mM perchlorate resulted in the oxidation of the medium and cessation of perchlorate reduction. The activity was revived by the addition of a reducing agent. The addition of air to the culture during perchlorate reduction immediately killed the process and continued aeration for 12 hours, thus permanently destroyed the ability of the culture to reduce perchlorate again in the future. The culture also reduced nitrite, nitrate, chlorite, chlorate, and sulfate. The presence of 10 mM nitrite or chlorite completely inhibited perchlorate reduction, whereas the same concentration of chlorate decreased the reduction rate. Concentration ranges of 3000 ppm, 5600 ppm, 6500 ppm, and 8900 ppm perchlorate were shown to be treatable in an 11-L anaerobic continuous stirred tank reactor (CSTR). Sustained volumetric degradation rates of 222 mg ClO_4/h per L with 99.9% removal efficiencies were observed [1187–1190].

Bacteria strains that were trained to thrive on perchlorate were either isolated from natural habitats or cultivated in the laboratory to be used in bioremediation projects.

A bacterium coded as strain HAP-1 was isolated from a municipal anaerobic digester due to its ability to reduce >7000 ppm perchlorate in wastewaters [1191]. The organism is capable of the dissimilatory reduction of perchlorate or chlorate to chloride

for energy and growth. It is a Gram-negative, non-sporeforming, obligately anaerobic, motile thin rod. Antibiotic resistance, utilization of carbon substrates, and utilization of electron acceptors by bacterium HAP-1 were similar to *Wolinella succinogenes*. The organism's 16S rRNA sequence was only 0.75% different from that of the strain type of *W. succinogenes*. The morphological, physiological, and 16S rRNA sequence data indicated that bacterium HAP-1 is a strain of *W. succinogenes* that can utilize perchlorate or chlorate as a terminal electron acceptor.

A low-cost biodegradation process was developed that converts ClO_4^- to harmless Cl^- that can be safely released into sewage treatment plants and then to the surface waters [1192–1194]. In 1995 a continuous-flow pilot system capable of treating up to 3700 L (1000 gallons) per day of effluent was designed, fabricated, and successfully tested at Tyndall AFB, Florida. In 1996, optimization studies were accomplished to transition this process to industry. This process can reduce the ClO_4^- concentrations from above 1% to below the detection limit (<0.5 ppm). In 1997, improved analytical methods enabled ClO_4^- detection down to 4 ppb. The action level in drinking water was set at 18 ppb. A pilot-scale bioreactor using a commercially available, water-soluble yeast extract (BYF-100) was able to reduce 3000 ppm ClO_4^- to below detectable levels with residence times as short as 12 hours. The bacterium capable of reducing ClO_4^- to Cl^- was identified as *Wolinella succinogenes*. Oxygen (dioxygen) will compete with ClO_4^- as an alternate electron donor. Cheese whey is more soluble than brewer's yeast and can be obtained at a fraction of the cost. Components of an existing pilot-scale demonstration unit were modified and integrated with existing waste treatment facilities at Thiokol near Brigham City, UT, treating 1700 L/d (450 gal/d) effluents containing 3000–5000 ppm ClO_4^- . Concentrations above 6000–10000 ppm appeared to inhibit ClO_4^- reduction. Actual effluents from operational processes were analyzed and found safe for discharge into an existing domestic sewage treatment plant. A very detailed and nicely illustrated summary of operating conditions and operating results of a demo plant at Tyndall AFB and a full-scale operation at Thiokol is presented in an interim report dated June 1998 [1195]. Feed concentrations were 20000–40000 ppm and effluent concentrations were rarely above 100 ppm. The Minuteman III remanufacture program and the Titan solid rocket motor disposal program will benefit directly from this technology. It was hoped that engineering modifications would allow optimized processing of the diluted perchlorate feed stream at four to eight hours residence time and reduce treatment costs to as low as \$0.15 per gallon of brine or \$0.85 per pound of perchlorate destroyed.

Although the fact that microbes reduce perchlorate or chlorate has been recognized for more than 50 years, only six organisms that can obtain energy for growth by this metabolic process were reported until 1999. As part of a study to investigate the diversity and ubiquity of micro-organisms involved in the microbial reduction of (per)chlorate, (per)chlorate-reducing bacteria (PRB) were identified in very diverse environments, including pristine and hydrocarbon-contaminated soils, aquatic sediments, paper mill waste sludges [1196], and farm animal waste lagoons [1197]. In all

of the environments tested, the acetate-oxidizing PRB represented a significant population. Sizes ranged from 2.31×10^3 to 2.4×10^6 cells per g of sample. Thirteen different PRB were isolated from these environments. All of these organisms could grow anaerobically by coupling complete oxidation of acetate to reduction of (per)chlorate. Chloride was the sole end product of this reductive metabolism. All of the isolates could also use oxygen as a sole electron acceptor, and most (but not all) could use nitrate. Alternative electron donors included simple volatile fatty acids, such as propionate, butyrate, or valerate, as well as simple organic acids, such as lactate or pyruvate. Washed cell suspensions of all of the PRB isolates could dismutate chlorite, an intermediate in the reductive metabolism of (per)chlorate, into chloride and molecular oxygen. Chlorite dismutation was a result of the activity of a single enzyme. The results of this study significantly increased the limited number of microbial isolates that were known to be capable of dissimilatory (per)chlorate reduction. This demonstrated the (until then) unrecognized phylogenetic diversity and ubiquity of the microorganisms that exhibit this type of metabolism.

In searching for bacteria that are capable of reducing perchlorate, and finding them already existing in perchlorate-contaminated aquifers, an interesting question has arisen: "Have these bacteria mutated to feed on the new oxygen donor only after the area was polluted by anthropogenic perchlorate, or did they exist before that time? If they previously existed, what else did they feed on?" [1198]. Many perchlorate-reducing bacteria can also use nitrate as an alternative electron acceptor. Phylogenetic analysis of DNA sequences of perchlorate-reducing bacteria placed them in the beta subdivision of proteobacteria.

Studies on the ubiquity and diversity of microbial (per)chlorate reduction done up until 2001 resulted in the isolation of 20 new strains of dissimilatory PRB. In-depth phylogenetic analysis revealed that all of the isolates were actually members of the Proteobacteria, with representatives in the alpha-, beta-, and gamma-subclasses. The majority of the new isolates were located in the beta-subclass and were closely related to each other and to the phototrophic *Rhodocyclus* species. An in-depth analysis of these organisms, which form two distinct monophyletic groups within the *Rhodocyclus* assemblage, revealed that two new genera, *Dechloromonas* and *Dechlorosoma*, can be proposed for these beta-subclass lineages which represent the predominant PRB in the environment [1199]. The type species and strains for these new genera are *Dechloromonas agitata* strain CKBt and *Dechlorosoma suillum* strain PST, respectively. In the end, it was found that more perchlorate-reducing bacteria occurred naturally in groundwaters than anyone had expected ten years earlier [1200].

An unusual perchlorate-respiring and hydrogen-oxidizing bacterium that grows with carbon dioxide as the sole carbon source was identified as *Dechloromonas sp. strain HZ* [1201]. Strain HZ is a Gram-negative, rod-shaped facultative anaerobe that was isolated from a gas-phase anaerobic packed-bed biofilm reactor treating perchlorate-contaminated groundwater. The ability of strain HZ to grow autotrophically with carbon dioxide as the sole carbon source was confirmed by demonstrating that

biomass carbon was derived from CO₂. Chemolithotrophic growth with hydrogen was coupled with the complete reduction of perchlorate (10 mM) to chloride. Strain HZ also grew using acetate as the electron donor and chlorate, nitrate, or oxygen (but not sulfate) as an electron acceptor. Phylogenetic analysis of the 16S rRNA sequence placed strain HZ in the genus *Dechloromonas* within the β subgroup of the Proteobacteria. The discovery of this novel perchlorate-reducing bacterium may lead to new and safer technologies for removing perchlorate from drinking water.

As part of a study to elucidate the environmental parameters that control microbial perchlorate respiration, the reduction of perchlorate by the dissimilatory perchlorate reducer *Dechlorosoma suillum* was investigated under a diverse set of environmental conditions [1202]. The tests demonstrated that perchlorate reduction via *D. suillum* occurred only under anaerobic conditions and was dependent on the presence of a trace of molybdenum. Perchlorate reduction was dependent on the presence of the enzyme chlorite dismutase, which was induced during metabolism of perchlorate. Anaerobic conditions alone were not enough to induce expression of this enzyme. Dissolved oxygen (DO) concentrations less than 2 mg/L were enough to inhibit perchlorate reduction via *D. suillum*. Similarly to oxygen, nitrate also regulated chlorite dismutase expression and repressed perchlorate reduction via *D. suillum*. Some bacteria can reduce nitrate simultaneously with perchlorate while others cannot. These studies demonstrated that microbial respiration of perchlorate is significantly affected by environmental conditions and that perchlorate reduction is directly dependent on the presence or absence of competing electron acceptors. A microbial treatment strategy can achieve and maintain perchlorate concentrations below the recommended regulatory level, but only in environments in which the variables can be controlled (preferably in an *ex-situ* bioreactor above ground).

Soil samples exhibited significant decreases in respiration activity in the presence of 100 or 1000 ppm perchlorate, simulating the dispersal of unburnt rocket propellant following a launch mishap [1137]. It is possible that the excess deposition of perchlorate to coastal soils following a flight abortion could decrease the rate that material is decomposed in soil, which could adversely affect the recycling of nutrients and eventually impact plant growth. The extent of this effect is controlled by the amount of propellant deposited, the average surface-to-volume ratio of deposited particles, and the number of particles deposited per area unit. Perchlorate dissolution data suggested that 100-ppm concentrations could be achieved in solutions in which volumes are restricted, and this may occur in stagnant soil water adjacent to dissolving chunks of propellant.

As of 2002, two full-scale *ex-situ* FBR systems were already treating perchlorate-contaminated groundwater in California and Texas [1203, 1204]. A third full-scale treatment system was scheduled for start-up in early 2002. The *in-situ* treatment of perchlorate was based on the addition of specific electron donors to groundwater and quickly evolved as a viable bioremediation technology. Earlier studies suggested

that perchlorate-reducing bacteria actually widely occur in nature, including in groundwater aquifers, and that these organisms can be stimulated to degrade perchlorate to below the current analytical reporting limit ($<4\text{ }\mu\text{g/L}$).

Some bacteria can use perchlorate as an electron acceptor while oxidizing a large range of electron-donating substrates. Scientists now recognize that perchlorate-reducing bacteria (PRB) are widely distributed in the environment and can be found at perchlorate-contaminated sites or in municipal sewage treatment plants. The pathways by which PRB degrade perchlorate are now well understood and biological treatment processes have been developed to remove perchlorate from contaminated water sources. Alternate electron acceptors in the water, such as oxygen and nitrate, compete with perchlorate removal. Until the year 2000, biological treatment systems using PRB had only been proven on the bench scale. After 2003 all pilot-scale tests were successful. A perchlorate bioreactor biological treatment was judged as a suitable method for soil remediation and water treatment of perchlorate-contaminated water [1205].

Perchlorate-reducing organisms were found to be ubiquitous in both uncontaminated and contaminated environments based on Most Probable Number determinations [1206]. The ability to stimulate and/or accelerate *in-situ* perchlorate degradation through donor addition has been studied in microcosm experiments. Acetate, molasses, canola oil, and oleate all served as successful electron donors. The interference of sulfate during perchlorate bioremediation is a concern. It was determined that the effect of sulfate on perchlorate degradation is dependent on both the relative concentrations of perchlorate and sulfate and on the microbial community composition at a site. Perchlorate-reducing organisms were isolated from several sites and studied with respect to characteristics that may affect *in-situ* biodegradation of perchlorate. All organisms isolated were facultative aerobes. All but two can reduce nitrate and none can reduce ferric iron or sulfate. Growth kinetic parameters were similar for all the isolates tested.

ClO_4^- reductase is the key enzyme in the pathway of ClO_4^- breakdown. ClO_4^- reductase from cell-free extracts of the ClO_4^- -respiring bacterium *perclace* was purified ten-fold by using ion-exchange and molecular exclusion fast protein liquid chromatography [1207]. The ClO_4^- reductase catalyzed the reduction of ClO_4^- . ClO_4^- reduction was achieved in the temperature range of 20 to 40 °C and with optimum activity at 25 to 30 °C and pH 7.5 to 8.0. Amino acid sequences of 22 tryptic peptides of the 35 kDalton ClO_4^- reductase subunit were obtained by using electrospray mass spectrometry. Comparison to GenBank protein analysis of the amino acid sequences revealed some similarity to reductases, dehydrogenases, and heme proteins.

The success of natural, *in-situ*, or controlled *ex-situ* perchlorate remediation is dependent on the presence and activity of dissimilatory (per)chlorate-reducing bacteria (DPRB) within a target site. To detect DPRB in the environment, two degenerate primer sets targeting the chlorite dismutase (*cld*) gene were developed and optimized [1208]. A nested PCR approach was used in conjunction with these primer sets to increase

the sensitivity of the molecular detection method. Screening of environmental samples indicated that all products amplified by this method were cld gene sequences. These sequences were obtained from pristine sites as well as contaminated sites from which DPRB were isolated. The use of these primer sets represents a direct and sensitive molecular method for the qualitative detection of PRB in the environment, thus offering another tool for monitoring natural attenuation. Sequences of cld genes isolated in the course of this project were also generated from various DPRB and provided the first opportunity for a phylogenetic treatment of this metabolic gene.

An extensive microcosm survey of perchlorate-contaminated sites was undertaken to assess the ability of indigenous micro-organisms to degrade perchlorate [1209]. Samples from 12 contaminated sites and from one pristine location were analyzed. Perchlorate was degraded to below detection limit in all electron donor-amended microcosms. Perchlorate-reducing micro-organisms (PRMs) were numerous at most of these sites. Sixteen distinct PRMs were isolated that were phylogenetically related to either *Dechloromonas* in the Beta Proteobacteria (9/16 isolates) or to *Azospirillum* in the Alpha Proteobacteria (7/16 isolates). The majority of previously isolated PRMs are in the Beta Proteobacteria related to *Dechloromonas* or *Dechlorosoma*. This study indicated that PRMs of the genus *Azospirillum* may be more prevalent at contaminated sites than the current record of isolates suggests. Cell yields, electron donor to perchlorate ratios, and maximum specific growth rates were similar among the isolates, which is similar to previously published values. The surprising finding is that microbial perchlorate reduction is ubiquitous, even at highly contaminated sites, and can be harnessed effectively for controlled and targeted bioremediation.

Surprisingly, bacteria are able to reduce perchlorate using metallic iron Fe(0) as the electron donor. Perchlorate was reduced reproducibly by using a mixed bacterial culture over a pH range of 7.0–8.9. Similar rates of perchlorate reduction were observed between pH 7.0 and 8.5, whereas significantly slower reduction occurred at pH 8.9. The addition of iron metal, Fe(0), to the mixed bacterial culture resulted in slower rates of perchlorate reduction [1210]. Only negligible perchlorate reduction could be achieved under abiotic conditions with Fe(0) alone in a reducing anaerobic medium. The addition of Fe(0) resulted in a rise in pH, as well as precipitation of Fe minerals that appeared to encapsulate the bacterial cells. The encapsulation of bacteria by Fe precipitates contributed to the inhibition of the bacterial activity independent of the effect of pH on bacteria. These results provide the first evidence linking the accumulation of iron precipitates at the cell surface to the inhibition of environmental contaminant degradation in the field. Fe(0) was not a suitable amendment to stimulate perchlorate-degrading bacteria. The bacterial inhibition caused by precipitation of reduced Fe species may be important in other combined anaerobic bacterial-Fe(0) systems. Furthermore, the inhibition of bacterial activity by iron precipitation may have significant implications for the design of *in-situ* bioremediation reactors for the treatment of perchlorate plumes.

In spite of problems with Fe(0) reported by previous investigators, experiments with microbial reduction of perchlorate with zero-valent iron (ZVI) continued in both batch and column reactors [1211, 1212]. Iron-supported mixed cultures completely removed 65 mg/L of perchlorate in batch reactors in eight days. The removal rate was similar to that observed with hydrogen gas (5%) and acetate (173 mg/L) as electron donors. Complete removal of perchlorate by iron-supported anaerobic cultures was also achieved in a bench-scale iron column with a hydraulic residence time of two days. Iron as an electron donor is inexpensive, safe to handle, and does not leave organic residuals in the treated water.

Genetic analyses and DNA sequencing have offered the first glimpse into the enzyme encoding genes which make the perchlorate-eating bacteria “tick” [1213, 1214]. The genomic analysis has offered tools for detecting, breeding, genetically engineering, and monitoring bacteria that are even more active than the ones we have been working with up to this time. The perchlorate reduction pathway consists of two key enzymes: perchlorate reductase and chlorite dismutase. Chlorite is very toxic and if it was not immediately removed as soon as it had formed, the perchlorate reduction process would come to a grinding halt.

It is now common knowledge that bacteria need a nutrient and an electron donor to effectively reduce perchlorate. A novel approach is to add a reversible redox chemical as a mediator to the bioreactor and two electrodes with DC current flowing between them. At the cathode, the redox chemical is reduced and the bacteria is converted to its oxidized state so it can be electrolytically reduced again. The reduction of perchlorate in the cathodic chamber of a bioelectrical reactor demonstrated that *Dechloromonas* and *Azospira* bacteria readily reduced 90 mg/L perchlorate with 2,6-anthraquinone disulfonate (AQDS) as a mediator [1215]. No perchlorate was reduced in the absence of cells or AQDS or in an open-circuit control. The results of these studies showed that biological perchlorate remediation can be facilitated through the use of a cathode as the primary electron donor.

We have seen that perchlorate-reducing bacteria can use elemental hydrogen or iron as electron donors, but the discovery of perchlorate-reducing bacteria that consume elemental sulfur added a new twist to the story of bioremediation [1216]. Sulfur pellets are inexpensive and can serve as excellent packing material for both *in-situ* and *ex-situ* bioremediation. The use of sulfur as an electron donor has the additional advantage that autotrophic bacteria tend not to produce high levels of matrix-clogging biomass. In both batch cultures and bioreactor systems, the microbial community thriving on elemental sulfur could reduce both high (5 ppm) and low (100 ppb) ClO_4^- concentrations to less than 4 ppb. Culture samples indicated a dominant perchlorate-reducing strain that is most closely related to *Dechloromonas* sp. strain JM (a member of the beta-proteobacteria).

A quantitative real-time PCR assay targeting the *pcrA* gene, encoding the catalytic subunit of perchlorate reductase, detected *pcrA* genes from perchlorate-reducing bacteria in three different genera and from soil microbial communities [1217, 1218]. Partial

pcrA sequences indicated differences in the composition of perchlorate-reducing bacterial communities following exposure to different electron donors.

The response behavior of three dissimilatory perchlorate-reducing bacteria to different electron acceptors (nitrate, chlorate, and perchlorate) was investigated using two different assays [1219]. The observed response was species-specific, dependent on the prior growth conditions, and was inhibited by oxygen. The bacteria were attracted toward nitrate when *Dechloromonas aromatica* strain RCB and *Azospira suillum* strain PS were grown with nitrate. When *D. aromatica* and *Dechloromonas agitata* strain CKB were grown with perchlorate, both responded to nitrate, chlorate, and perchlorate. When *A. suillum* was grown with perchlorate, the organism responded to chlorate and perchlorate but not nitrate. A gene replacement mutant in the perchlorate reductase subunit (pcrA) of *D. aromatica* resulted in a loss of the attraction response toward perchlorate but had no impact on the nitrate response. This demonstrates the unique ability of these organisms to distinguish between structurally analogous compounds, nitrate, chlorate, and perchlorate, and respond accordingly.

Bioremediation of perchlorate started with modest beginnings, first with *ex-situ* then with *in-situ* treatment. However, over the past two decades, it has grown into a substantial industry supported by numerous scientific publications. There are even several books published on this subject which provide a lot of detail for further study and with regards to the design of clean-up projects [1083–1086].

A 2001 report listed 65 contaminated sites where various decontamination techniques were being tested on a small experimental scale; 45 of these relied on bioremediation. The following discussion is subdivided into *ex-situ* and *in-situ* treatment efforts. While various abiotic and biotic processes have been utilized for *ex-situ* perchlorate clean-up, the *in-situ* perchlorate remediation has depended entirely on finding the right combination of bacteria and nutrients. Nutrients are needed that do not leave a residue in water that is intended for human consumption.

A mathematical model was developed to describe the biodegradation kinetics of perchlorate in the presence of nitrate and oxygen as competing electron acceptors [1220]. The rate of perchlorate degradation is described as a function of the electron donor (acetate) degradation rate, the concentration of competing electron acceptors, and rates of biomass growth and decay. The kinetics of biomass growth can be described using a simplified model, and inhibition factors can be incorporated to describe the influence of oxygen and nitrate on perchlorate degradation. Model predictions were compared to laboratory data obtained using *Azospira suillum*, a perchlorate-degrading strain isolated from groundwater. This strain is capable of utilizing oxygen, nitrate, or perchlorate as terminal electron acceptors. Combined with appropriate groundwater transport models, this model can be used to predict perchlorate biodegradation during *in-situ* remediation efforts.

Most of the publications summarized here deal with dilute perchlorate solutions. To treat wastewater containing much higher concentrations of perchlorate, a perchlorate reducing-bacterial consortium was obtained from enrichment cultures

grown on high-strength perchlorate (1200 mg/L) feed medium. This was characterized in a sequence batch reactor during a long-term operation [1221]. The consortium removed perchlorate in the batch reactor with high reduction rates ($35\text{--}90\text{ mg L}^{-1}\text{ h}^{-1}$) and stable removal efficiency over 200-day operations. The maximum specific perchlorate reduction rate ($q_{\max}$), half-saturation constant (K_s), and optimal pH range were $0.67\text{ mg-perchlorate mg-dry-cell-weight}^{-1}\text{ h}^{-1}$, $193.8\text{ mg-perchlorate/L}$, and pH 7–9, respectively. The perchlorate reduction yield was $0.48\text{ mol of perchlorate/mol of acetate}$. A clone library prepared using the amplicons of *cld* gene encoding chlorate dismutase showed that the dominant (per)chlorate reducing bacteria in the consortium were *Dechlorosoma sp.* (53%), *Ideonella sp.* (28%), and *Dechloromonas sp.* (19%).

Although ion exchange is a promising non-selective and incomplete disposal process, the disadvantage is that it merely transfers perchlorate from water to the resin. The perchlorate-laden spent resins require regeneration producing concentrated brine (6–12% NaCl) or caustic waste streams. On the contrary, biological reduction completely degrades perchlorate into O_2 and innocuous Cl^- . Numerous unique dissimilatory perchlorate-reducing bacteria have been isolated and detailed studies pertaining to their micro-biological, biochemical, genetics, and phylogenetic aspects have been undertaken, as summarized in a review article [1222].

The effects of nitrate and sulfate on the degradation behavior of perchlorate (ClO_4^-) in soils and sediments of natural environments were investigated [1223]. The lag time of both ClO_4^- and NO_3^- degradation was site-specific and depended on environmental conditions such as the content of organic substrate, NO_3^- concentration, initial ClO_4^- concentration, and prior ClO_4^- exposure. The lag time of ClO_4^- degradation at an initial concentration of 5 mg/L ranged from one-and-a-half to 34 days, depending on environmental conditions, and its rate constant ranged from 0.003 d^{-1} to 0.094 d^{-1} . The lag time of NO_3^- degradation ranged from half a day to 16 days, and its rate constant ranged from 0.017 d^{-1} to 0.179 d^{-1} , indicating that NO_3^- degradation rate is relatively higher than that of ClO_4^- . Nitrate does prolong the lag time of ClO_4^- degradation, which may account for the persistence of ClO_4^- in the environment. The results revealed that micro-organisms can degrade ClO_4^- in sediments and soils, and that the degradation efficiency is influenced by the availability of an organic substrate.

Bioremediation of perchlorate-contaminated water by a heterotrophic perchlorate reducing bacterium creates an electron acceptor-donor system. The perchlorate reduction activity by *Azospira sp. KJ* was tested at multiple pH levels and with different electron acceptor and donor systems [1224]. Perchlorate reduction was drastically inhibited at the pH 6.0 and the maximum reduction of perchlorate by *Azospira sp. KJ* was observed at a pH value of 8.0. Perchlorate reduction was completely inhibited by the additional O_2 in the $\text{ClO}_4^-/\text{O}_2$ acceptor system. The reduction proceeded sequentially with ClO_3^- first, ClO_4^- later, and NO_3^- last.

8.9.3 AP Removal via *Ex-Situ* Bioremediation

Aerojet operated the Rancho Cordova site near Sacramento, CA, producing rocket propellants for nearly 60 years. There had been perchlorate releases at various propellant processing installations on the 8500-acre site. In the late 1980s, Aerojet was the first company to begin perchlorate clean-up operations. They designed a packed bed recycle reactor. Approximately ten years later, Aerojet designed and built the first full-scale, above-ground treatment facility using a fluidized-bed reactor [1225]. Ethanol was used as the electron donor. As of 2008, the FBR was still in operation at the site, treating 10 million gallons of groundwater daily. Aerojet tested microbes collected from various areas for their perchlorate reducing ability. One type of microbe was able to work with starting concentrations as high as 100 mg/L using the ethanol or manure as electron donor. Another experiment used ethanol or molasses as the electron donor.

As of 2006, full-scale fluidized bed *ex-situ* bioreactors were working at five different locations, removing perchlorate from 30 million liters of groundwater every day. In addition to this, two full-scale suspended growth bioreactors were used to treat higher-concentration industrial wastewater at rocket propellant installations. With the addition of electron donors (lactate, acetate, citrate, ethanol, vegetable oil, or hydrogen gas), the bacteria are able to reduce the perchlorate concentration from several hundred ppm to below the legal limit in effect at the time (4 µg/L). *In-situ* bioremediation demonstrations were lagging behind the *ex-situ* processes because they are more difficult to control in remote areas underground and under the influence of a variety of environmental factors that are difficult to control (soil conditions, climate, precipitation).

Perchlorate removal using anaerobic bioreactors has been proven for on-site stationary applications and at the pilot-plant level.

The results of prior lab studies at Tyndall AFB were used to design, fabricate, and demonstrate a pilot-scale complete AP biodegradation bioreactor system using actual effluent from the demilitarization of Minuteman stage 2 propellant washout supplied by Aerojet's Propulsion Division [1192, 1226]. Using an anaerobic 6000-L (1600 gal) reactor in conjunction with the HAP-1 micro-organism discovered at AFRL, it was demonstrated in both tests at both Tyndall AFB and Thiokol-Morton (Utah) that the virtually complete destruction of AP in wastewaters was possible. The operating costs for the bioreactor system revealed that fixed costs (electricity, maintenance, and labor) were at a minimum for 2000–4000 ppm perchlorate concentrations.

A bacterium, *perclace*, has been shown to reduce perchlorate to less than the detection limit of 0.004 mg/L when grown in a bioreactor on acetate under anaerobic conditions [1227]. In batch studies, the presence of nitrate did not significantly hinder the reduction of perchlorate. The ability of *perclace* to remove nitrate and perchlorate from groundwater in a flow-through system was studied in Celite-packed 300 mL columns. At a flow rate of 1 mL/min, perchlorate was removed from 0.738 mg/L to less than detectable levels. When the flow rate was 2 mL/min, 92 to 95% of the perchlorate

was removed. Analysis of bacterial biomass at the completion of the study revealed that most of the bacterial growth was concentrated in the inlet area of the column. A circulating pump was added with the idea that passing the groundwater multiple times through the bacterially active zone might increase the efficiency of the column. In this experiment, perchlorate in groundwater was reduced from 0.550 mg/L to non-detectable levels at a flow rate of 1 mL/min within several days.

Two different stationary perchlorate bioreactors were compared as part of a design study: a heterotrophic, acetate-fed consortium of bacteria and an autotrophic, hydrogen-utilizing consortium of bacteria [1228]. The heterotrophic system was assumed to use *perclace* while the autotrophic system was assumed to use a consortium of five different organisms. Both systems would be capable of removing nitrate and perchlorate simultaneously. The bacteria were tested in a bench reactor with water pumped from two contaminated wells in the San Gabriel Valley in California. One contained 200 µg/L and the other contained 550 µg ClO_4^- /L. The autotrophic system has the advantage that the electron donor (hydrogen gas) is easy to meter in, whereas accidental overdosing of organic carbon sources may cause biofouling and may require additional clean-up of the effluent.

Abatement and remediation of perchlorate in soil and groundwater were achieved using a biological permeable reactive barrier system at the McGregor, Texas Naval Weapons Industrial Reserve Plant [1229]. A biological FBR installed at the LHAAP in Karnack, Texas, has successfully reduced perchlorate levels in groundwater at the site to below the detection limit (<4 ppb) [1082]. Biological FBR are being used to remove perchlorate, with a 99.99% efficiency from contaminated groundwater at the Kerr-McGee site in Henderson, Nevada [1097].

Bioremediation of perchlorate-contaminated water was tested at several locations in pilot-scale demonstration projects. Suspended growth, fixed bed, and fluidized bed bioreactors have been used to degrade perchlorate at influent concentrations ranging from 0.13 to 7750 ppb [1089]. The biological degradation of perchlorate was examined using a laboratory-scale, autotrophic, packed-bed biofilm reactor [1230]. The reactor was operated in unsaturated-flow mode and continuously fed water containing perchlorate and a gas mixture of hydrogen (5%) and carbon dioxide at a retention time of 1.5 minutes. In the absence of nitrate, perchlorate removal rate in the reactor was found to be first order with respect to perchlorate concentration. Perchlorate removal rates in the hydrogen feed were found to be comparable to rates measured by others using organic electron donors such as acetate. When nitrate was present in the water, similar perchlorate removals were achieved despite nitrate concentrations three orders of magnitude higher than perchlorate concentrations. Perchlorate was removed by an average of $25 \pm 5\%$ per passage from a typical perchlorate-contaminated groundwater containing 73 ppb of perchlorate and 21 ppm of nitrate. Research in this area was very active for several decades and continues to grow [1231]. Perchlorate can be reduced in a hydrogen-based membrane biofilm reactor [1122, 1232, 1233].

The use of GAC as a biofilm support medium was compared to that of sand for perchlorate bioremediation in acetate-fed FXB bioreactors [1234–1236]. GAC can physically adsorb perchlorate. Perchlorate was reduced in sand column bioreactors from 20 mg/L to below the detection limit ($<4\text{ }\mu\text{g/L}$) at empty-bed contact times (EBCTs) as low as 43 minutes (detention time of 18 minutes). GAC-packed columns performed similarly for the first ten days, however, after the column was backwashed to redistribute biofilm-coated particles in the reactor, reactor efficiency was substantially reduced due to perchlorate desorption. Increasing the concentration of acetate in the feed partially restored reactor performance. It was concluded that fixed-film reactors for perchlorate-contaminated waters should contain non-perchlorate-adsorbing packing in the reactor.

Instead of packed-bed columns, the same support media (GAC or sand) can also be used in fluidized bed bioreactors [1237]. GAC FBR's achieved a higher level of perchlorate reduction than sand-filled FBR's. Ethanol/methanol mixtures worked better as electron donors than methanol by itself (see [1238–1240] also).

The clean-up of groundwater from many military proving grounds and firing ranges is complicated by the fact that the water contains not only perchlorate but also RDX and other explosive residues [1241]. The *ex-situ* remediation of both perchlorate and explosives in groundwater at the Camp Edwards Training Area on the Massachusetts Military Reservation was using a biological fluidized bed reactor (BFBR). Perchlorate and RDX were present in the groundwater at concentrations up to $300\text{ }\mu\text{g/L}$ and $200\text{ }\mu\text{g/L}$, respectively. This case presents challenges for treatment at significantly lower concentrations and for groundwater commingled with explosives such as RDX. The challenges for the BFBR treatability studies were to remediate groundwater in the operable units to less than $1.5\text{ }\mu\text{g/L}$ for perchlorate and to show significant degradation of RDX.

A bioreactor was operated continuously in a remote field location for more than two years with a stable ecosystem of indigenous organisms and was following discovery that they are capable of removing perchlorate (14 to $27\text{ }\mu\text{g/L}$) and nitrate (48 mg/L) from contaminated groundwater [1242]. Total community DNA was extracted and purified from 10-g sediment samples. Analysis by denaturing gradient gel electrophoresis of short, 16S rDNA, polymerase-chain-reaction products was used to identify dominant micro-organisms. Of the 17 dominant bands sequenced, most were gram-negative and capable of aerobic or anaerobic respiration with nitrate as the terminal electron acceptor (*Pseudomonas*, *Acinetobacter*, *Halomonas*, and *Nitrospira*). Isolates were identified from the Proteobacteria class. This is known for its ability to reduce perchlorate. Initial bacterial assessments of sediments confirmed the prevalence of facultative anaerobic bacteria capable of reducing perchlorate and nitrate *in-situ*.

The operation of bioreactors can be improved by recirculating part of the effluent for a second pass. The effect of partial effluent recirculation on perchlorate reduction in a nominally plug-flow fixed biofilm reactor was studied for two different

influent concentrations of ten and 400 $\mu\text{g/L}$ at low hydraulic loading rates (1.9 and 37.5 $\text{m}^3 \text{m}^{-2} \text{d}^{-1}$ without and with recirculation, respectively) and after a step increase in perchlorate concentration to 1000 $\mu\text{g/L}$ at the higher hydraulic loading rate (5 and 100 $\text{m}^3 \text{m}^{-2} \text{d}^{-1}$ without and with recirculation, respectively) [1243]. Complete perchlorate reduction was sustained for influent concentrations of 400 and 10 $\mu\text{g/L}$ in both flow regimes at the lower hydraulic loading rates. The recirculation bioreactor adjusted itself more rapidly to increased hydraulic and perchlorate mass loading rates while maintaining significantly lower effluent perchlorate concentrations compared to the PFR: This was 16 $\mu\text{g/L}$ versus 46 $\mu\text{g/L}$, respectively, although complete perchlorate removal was not achieved in either flow regime following 21 days of acclimation to the higher loading.

When ion exchange or membrane technologies are used to remove perchlorate from water, the question remains of how to get rid of the brine. Feeding the brine to stationary bioreactors can increase the overall attractiveness of ion exchange or membrane processes by eliminating the need to dispose of a concentrated perchlorate/brine solution.

Inhibition of the biodegradation of concentrated perchlorate (200, 500, 1100, 1700, and 2400 mg/L as ClO_4^-) solutions by increasing salinity was investigated using two microbial cultures, return activated sludge (RAS) and ADS, both isolated from a domestic wastewater treatment plant [1244]. Experiments were performed in wastewaters containing various sodium chloride concentrations ranging from 0 to 4% (w/v) NaCl (ionic strength: 0.14–0.8 M, TDS: 5.3–42 g/L) at near-neutral values of pH (6.7–7.8). Perchlorate biodegradation was sustained through stepwise acclimation to increasingly higher salinity until it failed. The ADS culture was capable of reducing perchlorate at salinities up to 4% NaCl, while the RAS culture exhibited complete inhibition of perchlorate degradation at 4% NaCl as the result of either a toxic effect or enzyme inactivation of the perchlorate-reducing microbes. It was concluded that biological reduction of concentrated perchlorate wastewaters using either RAS or ADS acclimated cultures is feasible up to 3% or 4% NaCl, respectively.

Autohydrogenotrophic bacteria were cultured in a membrane reactor and were capable of removing 3.6 mg/d of perchlorate in the presence of excess hydrogen (99% removal) [1245]. The reactor was successful in treating average influent perchlorate concentrations of 532 $\mu\text{g/L}$ down to the level of 3 $\mu\text{g/L}$. Perchlorate removal ranged from 100 to 50% per pass. The kinetic rate of perchlorate degradation was 1.62 h^{-1} . The significant degradation of perchlorate in these samples indicates the ubiquity of perchlorate-reducing organisms. Nitrate was simultaneously removed (greater than 90% removal). The unwanted growth of sulfate-reducing organisms in the reactor adversely affected perchlorate removal efficiency.

The influence of backwashing on biological perchlorate reduction was evaluated in two laboratory scale FXB biofilm reactors using 1- or 3-mm glass beads as support media [1246]. Perchlorate concentration in the feed was 50 $\mu\text{g/L}$ and 2 mg/L acetate was added as the electron donor. Perchlorate removal was evaluated at various influ-

ent DO concentrations. The immediate effect of backwashing depended on influent DO concentrations. With influent DO concentrations of 1 mg/L, backwashing resulted in a brief (<12 h) increase of effluent perchlorate concentrations up to 20 µg/L but with DO = 3 mg/L, perchlorate reduction ceased altogether.

The former Bermite site north of Los Angeles, CA, was used to manufacture various explosives, pyrotechnics, and igniters containing perchlorates, spilling some in the process. Remediation of perchlorate in soil and groundwater was performed to allow planned redevelopment activities to proceed [1247]. The general approach to perchlorate remediation of shallow soil at the site included excavation of affected soils followed by *ex-situ* bioremediation. Glycerin was chosen for use as an electron donor because of its stability, safety, low cost, and regulatory acceptance. However, full-scale bioremediation operation with glycerin initially resulted in inconsistent results despite consistent perchlorate biodegradation observed in treatability study microcosms. To eliminate the inconsistency and optimize the biotreatment process, additional studies were performed in the field on parallel tracks to determine crucial factors that influence the inconsistent breakdown of perchlorate in site soils. Total Kjeldahl nitrogen was determined to be a significant factor limiting perchlorate biodegradation. The addition of di-ammonium hydrogen phosphate resulted in consistent and complete perchlorate removal, generally within two weeks of incubation, and with a median destruction rate of about 200 µg kg⁻¹ d⁻¹. Soil processing rates were gradually increased over the year, and eventually ~2000 to 2500 tons of soil were being processed per day. The total unit treatment cost for the process was approximately \$35/ton.

Batch experiments were conducted to investigate the kinetics of perchlorate reduction by heterotrophic and mixed perchlorate-reducing bacteria [1248]. Substrate-utilizing and cellular maintenance models were employed to fit the experimental data for microbial perchlorate reduction. The half-saturation constant, K_s , obtained in this study was below 0.1 mg/L, which indicated that perchlorate-reducing bacteria are effective at utilizing low concentrations of perchlorate. A study of the effect of pH on the kinetics of microbial perchlorate reduction showed that perchlorate reduction occurred throughout the pH range from 5.0 to 9.0. The rates of perchlorate removal using a unit mass of bacteria were significantly different at various pH values with a maximum rate at pH 7. The variation of $q_{\max}$ with pH was described well with a Gaussian peak equation. This equation is expected to be applicable for practical purposes when pH effects need to be considered.

Two other chlorate- and perchlorate-reducing bacteria strains were isolated from a swine waste lagoon and grown with acetate as the sole electron acceptor [1249]. Even though the two strains differ morphologically, their physiologies are very similar and optimum growth is observed on short-chain fatty acids.

On closer examination, it was noted that novel perchlorate-reducing bacteria are discovered all the time, in this case from enrichments conducted under conditions different from all those previously tested [1250]. The use of perchlorate and other electron

acceptors distinguished strains MPT and CR from *P. limicola* physiologically. Strain LT-1T had differences in electron donor utilization and optimum growth temperatures from *A. caeni*. Strains LT-1T and MPT are the first bacteria to be described in the Betaproteobacteria outside of the *Dechloromonas* and *Azospira* genera. On the basis of phylogenetic and physiological features, strain LT-1T represents a novel genus in the *Rhodocyclaceae*; strain MPT represents a novel species within the genus *Propionivibrio*.

In February 2007, a ten-month demonstration study was initiated in Rialto, CA, to treat perchlorate-contaminated groundwater using FXB bioreactor technology [1251]. Two first-stage parallel FXB bioreactors (F120 with a 3.9-ft bed depth and a 2-ft diameter, and F130 with a 4.7-ft bed depth and a 2-ft diameter) treated groundwater to remove perchlorate. Effluent from these reactors was dosed with hydrogen peroxide to reoxygenate and oxidize residual organics and hydrogen sulfide. The reoxygenated water was then passed through a FXB biofilter (F150) to oxidize any remaining organics and sulfide and to remove turbidity. Chlorine was then dosed to the effluent of the biofilter as a final disinfection step. A bench-scale FXB bioreactor was also constructed to test operating conditions of a bioreactor on a smaller scale. Experience gained during the demonstration study formed the basis for the design and operating cost estimate of a full-scale unit [1252].

Denitrifying packed-bed bioreactors fed with perchlorate and nitrate allowed for the examination of the impact of a variety of salinity conditions (up to 10 wt.-% NaCl) on the complete perchlorate and nitrate removal capacity of the reactors using activated sludge taken from a municipal wastewater treatment plant [1253]. Based on the evaluation of the microbial community in the bioreactor using cloning analysis, *Clostridium* sp. and a *Rhodocyclaceae* bacteria were identified as the dominant population. This suggests that they may be tolerant to high salt concentrations and can reduce both nitrate and perchlorate under such conditions.

Denitrifying up-flow packed-bed bioreactors can simultaneously remove nitrate and perchlorate from ion-exchange regenerant brines. A continuous-flow reactor, which was inoculated with denitrifying bacteria obtained from a municipal wastewater plant, completely removed perchlorate as well as nitrate in adverse conditions with up to 10% salinity [1254]. Variables that affected the rate of contaminant removal were acetate (as an electron donor) and sulfate (as a competing electron acceptor) concentrations, which were both added at different salinities. Lower carbon loading decreased the nitrate and perchlorate reductions. However, increased sulfate loading did not decrease the reductions of nitrate and perchlorate.

Electron acceptors such as nitrate or sulfate ions may competitively inhibit the reduction of perchlorate in brine in continuous up-flow packed bed bioreactors. A study of the effect of pH and hydraulic retention time (HRT) on the reduction of perchlorate at high salinity revealed that the reduction of perchlorate was only moderately influenced by nitrate (under 163 mg NL^{-1}), implying that there was no significant microbial competition for electron acceptors [1255]. As a result of microbial diversity,

there were few differences between microbial communities fed with a variety of media, suggesting that most nitrate-reducing bacteria are able to reduce perchlorate at high salinity. Reduction of perchlorate was almost complete at relatively high sulfate levels (1000 mg L^{-1}), neutral pH (6–8) levels, and relatively long HRTs (>10 hours).

8.9.4 AP Removal Using *In-Situ* Bioremediation

Active *in-situ* bioremediation techniques involve the continuous pumping and metering of soluble electron donors underground to sustain the ongoing perchlorate reduction. Now we even have a book devoted exclusively to the *in-situ* bioremediation of perchlorate in groundwater [1086]. This book contains 11 chapters, all of which are individually referenced in the current book at hand, including a chapter on active bioremediation [1256]. Semi-passive systems inject soluble electron donors only periodically and rely on natural diffusion and downgradient motion to catch up with the contaminant to be reduced [1257]. Similar to an active system, groundwater is recirculated between an injection and extraction well, but only for a short time (several days) to distribute the electron donor. Following this, the pumps are turned off and the system is left to its own devices for a longer time (several weeks to several months). Injection and extraction wells can be arranged so as to create a biologically active barrier perpendicular to the groundwater flow. The equipment needed for a semi-passive system can be mobile and can be moved from well bore to well bore to serve a larger area. Semi-passive systems require fewer injection wells and are not as susceptible to biofouling as active systems. One of the recommended soluble electron donors for active or semi-passive systems is sodium lactate which does not leave any residue. Passive systems install slow-release electron donors in trenches, well bores, or direct-push situations without pumping any liquids. Some of the passive systems have used emulsified edible vegetable oils through grid injection [1258] or installed a barrier ditch filled with wood chips [1259] or mulch [1260] as a permeable biologically active barrier perpendicular to the direction of groundwater flow. The vegetable oil will slowly hydrolyze, releasing glycerol and long-chain fatty acids which are good electron donors. A passive system has low operational and maintenance costs but may not be the fastest approach to get an unacceptable situation under control. Because the organic substrate must be distributed in the contaminated strata, this method is limited to the treatment of shallow plumes.

At the Naval Surface Warfare Center, Indian Head, MD, the Navy had demilitarized rocket motors. This was accomplished via washout using water for several decades. Some of the wastewater had escaped into the ground. This site was selected to conduct the first *in-situ* perchlorate bioremediation field test by connecting a water recirculation design to distribute lactate solution in a shallow aquifer at the site [1261, 1262]. Two field plots were installed, each consisting of two injection wells and two extraction wells. Groundwater was amended with lactate and pH buffer and reinjected into the ground. The initial perchlorate concentration was 171 mg/L . Over the course

of a few months, the perchlorate concentration in eight of the nine wells decreased by more than 95% from the original value. Five wells reached perchlorate levels below 1 mg/L and two wells below 5 µg/L. Nitrate levels were also reduced very effectively and dropped to non-detectable levels in seven weeks.

Recirculation of the contaminated water, bringing it to the surface and reinjecting it into the ground, requires a substantial amount of pumping energy. If one attempts to inject the nutrient and electron donor solution directly into the aquifer holding the contaminated perchlorate solution, the vicinity of the injection well often develops competing bacterial flora. Biofouling may require frequent cleanout of clogged passages or the drilling of a new injection well at a different location. A better understanding of the competing bacteria is required to optimize the process [1263, 1264] (see [1265] also).

Perchlorate degrading bacteria are actually ubiquitous at most perchlorate-contaminated underground sites. They just lack the proper nutrients to propagate and to do a better job at reducing the perchlorate level *in-situ*. One of the objectives of ongoing *in-situ* remediation studies is to find the proper nutrients to keep the perchlorate-eating bacteria happy and working [1225, 1266].

Bacteria depend on electron donors (reductants) to be able to reduce perchlorate. Electron donors have to be present to accelerate biodegradation and bioremediation of perchlorate. If the natural environment (plants, decaying organic material, swamp gas) does not provide any of these, the soil in sites undergoing perchlorate clean up must be amended with electron donors. Electron donors tested at various *in-situ* bioremediation sites include hydrogen gas, or solutions or suspensions of acetate, lactate, corn syrup, ethanol, vegetable oil, citric acid, cow manure, and chicken manure.

Poplar trees are being tested for phytoregeneration of perchlorate-contaminated soil. Root homogenate from poplar trees stimulated perchlorate degradation in microcosms of soil and water samples collected at a perchlorate contaminated site (the LHAAP, located outside Karnack, Texas) [1267]. Perchlorate-degrading bacteria were able to thrive when given root products as the sole exogenous source of carbon and electron donors. The ability of root products to drive perchlorate respiration by using bacteria is vital for the successful achievement of perchlorate rhizodegradation in conjunction with phytoremediation.

In another clean-up project at LHAAP, active and semi-active *in-situ* bioremediation approaches were demonstrated and compared for cost and efficiency [1268, 1269].

It was discovered that the addition of hydrogen gas greatly enhances the ability of bacteria to reduce perchlorate. Two hydrogen-utilizing perchlorate-degrading bacteria have been isolated following discovery that they are capable of using inorganic carbon for growth. These are the first perchlorate-degrading autotrophs isolated from a perchlorate-contaminated site [1270]. These autotrophic bacteria are within the genus *Dechloromonas* and are the first *Dechloromonas* species that are microaerophilic and incapable of growth at atmospheric oxygen concentrations. Measured hydrogen thresholds were higher than for other environmentally sig-

nificant, hydrogen-utilizing, anaerobic bacteria (e.g., halorespirers). The chlorite dismutase activity of these bacteria was greater for autotrophically grown cells than for cells grown heterotrophically on lactate. These bacteria were fed fumarate as an alternate electron acceptor, which is the first report of growth on an organic electron acceptor by perchlorate-reducing bacteria.

A unique method for perchlorate or nitrate bioremediation in the vadose zone is a combination of an *in-situ* bioreactor with reducing (electron donor) gas injection to facilitate the action of anaerobic bacteria feeding on perchlorate and nitrate [1271]. The use of gaseous instead of liquid reductants has the advantage that they diffuse better through low-permeability soils and any excess disperses without a trace. This technique is called *Gaseous Electron Donor Injection Technology* and is an anaerobic variation of petroleum hydrocarbon bioventing. It involves injecting electron donor gases or vapors, such as hydrogen or ethyl acetate, into the vadose zone to stimulate biodegradation of nitrate and perchlorate. In lab studies, nitrate removal was best promoted by ethyl acetate. Up to 39% perchlorate removal was achieved with ethanol but this was limited by insufficient incubation time. Hydrogen, 1-hexene, ethyl acetate, and liquefied petroleum gas were tested as electron donors at different soil moisture conditions. Under high soil moisture (16 wt.-%) conditions, complete or partial perchlorate degradation was achieved with all of the tested electron donors except for ethyl acetate. Hydrogen was the most promising of the tested electron donors, achieving complete perchlorate degradation with first-order rate constants ranging from 0.13 to 0.20 d⁻¹ and reducing concentrations to non-detectable levels within 35 to 42 days [1272]. Aerojet has rehabilitated the inactive 8500-acre Rancho Cordova, CA, site by injecting a mixture of hydrogen (electron donor) with propane, nitrogen, and carbon dioxide through a specially configured injection well. After eight months of continuous treatment, final soil samples proved that this process successfully remediated contaminants at the site. The amount of perchlorate in the soil was reduced by 93% and nitrate was reduced by 94%.

A field demonstration was conducted to evaluate the *in-situ* bioremediation treatment of perchlorate using a horizontal flow treatment well system to mix electron donor into perchlorate-impacted groundwater [1273, 1274]. The objectives of this project were to demonstrate that *in-situ* biological perchlorate treatment is feasible in the field using electron donor addition and that perchlorate concentration can be lowered down to 4 µg/L. Related problems are that biofouling must be effectively controlled by measures that are easily implemented and that co-contaminants, including nitrate and trichloroethene, can be treated using the same technology.

In-situ bioremediation has many advantages, such as reduced costs and time for clean up, as compared to pump-and-treat [1256]. Alternatives for active *in-situ* bioremediation of perchlorate are (a) natural attenuation (dilution), (b) passive system using mulch biowall to intercept plume, (c) passive biobarrier using an injection of semi-soluble electron donors such as vegetable oil, and (d) an active or semi-passive system

with injection of soluble electron donors in recirculated groundwater extracted from downgradient [1275, 1276].

In the end, it may be the cost of installing and operating an *in-situ* bioremediation system that decides which system should be used [1277]. This includes not only the initial capital investment but also the operational and maintenance expenses for which a budget must be set up. Because this is a relatively new technology, the experience base is quite limited.

8.9.5 AP Removal via Phytoremediation

Phytoremediation, which refers to the use of plants and their associated microbes and root exudates for environmental cleanup, has gained acceptance in the past 20 years as a cost-effective, non-invasive alternative or complementary technology for engineering-based remediation methods. The selective revegetation of a disturbed and contaminated site with plants that have the ability to reduce perchlorate to chloride is another environmentally friendly method for bioremediation. Some plants (e.g., willows) have the ability to reduce perchlorate to chloride [1278]. Hydroponically grown woody and aquatic plants were observed to remove perchlorate from aqueous solutions via two mechanisms: an initial slow uptake and transformation of perchlorate in the plant tissues (phytodegradation) followed by very rapid removal of perchlorate from solutions in the root zone (rhizodegradation) with substantial contributions by bacteria living in the root zone [1279]. Exudates secreted from the plant roots supplied nutrients for the perchlorate-reducing bacteria.

Two types of hydroponic bioreactors were used to investigate the mechanistic changes during phytoremediation of perchlorate under different root-zone conditions [1280]. The bioreactors included (1) an aerobic ebb-and-flow system planted with six willow trees and (2) individual willow trees grown in sealed root-zone bioreactors. Radiolabeled (^{36}Cl -labeled) perchlorate was used as a tracer in a subset of the sealed bioreactor experiments to quantify the contribution of phytodegradation and rhizodegradation mechanisms. Slower rates of phytoremediation by uptake and phytodegradation were observed under high nitrate concentrations and aerobic conditions, which allowed perchlorate to persist in solution and resulted in a higher fraction uptake by the plant. The results of this study indicate that the root-zone environment of plants can be manipulated to optimize rhizodegradation and to minimize undesirable processes such as uptake, temporal phytoaccumulation, and slow phytodegradation during phytoremediation of perchlorate. This can also be done in hydroponic bioreactors in greenhouses instead of in the field [1281].

The potential to use native (*Salix exigua*) and exotic (*Tamarix ramosissima*) phreatophytes to remediate perchlorate from arid riparian environments was investigated by conducting a hydroponic greenhouse experiment [1282]. *Salix exigua* and *Tamarix ramosissima* exposed to AP at concentrations of 10 mg/L and 100 mg/L removed 15 to 22% perchlorate mass from hydroponic solution, with 55 to 64% of removal

being taken up into plant tissue. Total perchlorate taken up by plants or removed from solution was not significantly different between species on a mass or oven-dry plant weight concentration basis. Significant differences in tissue specific uptake, however, were detected, with *Salix exigua* accumulating 78 to 87% of perchlorate in the leaf and *Tamarix ramosissima* exuding 84 to 87% of uptake onto leaf surfaces. Burning the dried leaf tissue resulted in no detectable perchlorate in the ashes.

The influence of biostimulation using dissolved organic carbon (DOC) on rhizodegradation of perchlorate and plant uptake was studied under greenhouse conditions using soil and hydroponic bioreactors [1283]. One set of bioreactors planted with willow (*Salix babylonica*) plants were spiked with 300 mg/L DOC in the form of chicken manure extract, whereas a second set was not treated with DOC. A similar experiment without willow plants was run in parallel to the planted bioreactors. The planted soil bioreactors amended with DOC reduced perchlorate from 65.8 to 2.7 mg/L in 21 d for humic soil (95.9% removal) and from 69 to 0.06 mg/L for sandy loam (99.9% removal) in 11 days. Non-planted DOC-treated soil bioreactors also achieved complete perchlorate removal in six and eight days for humic and sandy loam, respectively. Both planted and non-planted soil bioreactors without DOC removed >95% perchlorate within eight days. Planted soil bioreactors respiked with perchlorate repeatedly reduced perchlorate to non-detectable levels in six days. Persistence of perchlorate in the solution of planted hydroponic bioreactors without DOC amendment suggested that natural DOC from the plant exudates was not enough to biostimulate perchlorate-reducing microbes. The hydroponic bioreactor study provided evidence that DOC is a limiting factor in the rhizodegradation of perchlorate.

Radiolabeled perchlorate was used to find that, in planted systems, as much as 11.7% of the influent perchlorate mass was taken up into the tree and 82% of the perchlorate taken up was accumulated in the leaves [1284]. The plant contribution to total perchlorate removal in non-bioaugmented low organic carbon soil was 39%, with the balance of the removal being attributed to microbial reduction. In bioaugmented soil, the microbial contribution to perchlorate removal was increased. Just planting poplar trees decreased the diversity of perchlorate reducers in the soil. At the increased oxidation-reduction potential observed in planted high organic carbon soil, the non-perchlorate-reducing bacteria appear to outcompete the perchlorate reducers and perchlorate removal is decreased. This means that perchlorate remediation in high organic carbon soil does not benefit from planting hybrid poplar trees but that remediation in low organic carbon soil is stimulated by planting and bioaugmentation.

8.9.6 AP Removal via Membrane Filtration

Although ion exchange and biological reduction are the most frequently used technologies for water purification, other technologies such as membrane filtration and electrodialysis may offer advantages under certain environmental

conditions [1285]. Membrane-based purification methods can be divided into three categories: **(1)** Reverse osmosis, **(2)** nanofiltration, and **(3)** electrodialysis. Reverse osmosis involves forcing water through a semiporous polymer membrane. In reverse osmosis, artificial pressure is applied on one side of the membrane, thus forcing water to migrate through the membrane wall, leaving perchlorate and most other dissolved salts behind. This technique is also used for desalination of seawater. Nanofiltration is a similar technique using membranes with slightly larger pores. However, fouling of the membrane filters remains a concern for both reverse osmosis and nanofiltration technologies. The membrane process produces two streams: the filtrate or permeate, which is nearly deionized water, and the brine concentrate, which has to be disposed of in another manner. This process could be used for point-of-use systems, such as home water purification or small-scale water treatment where sufficient electrical energy is available to drive the compressors.

8.9.7 AP Removal via Electrochemical Reduction

Until recently, few studies had looked at the electrochemical reduction of aqueous perchlorate. As such, there is only limited data in existing literature regarding the removal of chlorate from water. Why though, when all perchlorate is produced via electrochemical oxidation, should the reaction not be reversible?

The first step of electrochemical reduction is

Further reduction of chlorate to chloride would require an elevated electrode potential:

Instead of generating oxygen at the anode, it is also possible to depolarize a catalytic anode by bubbling hydrogen gas around it, while perchlorate is reduced at the cathode like in a fuel cell.

The electrochemical reduction of perchlorate anion has been studied in an electrolysis cell with a nickel working electrode and a platinum counter electrode in concentrated solutions of HClO_4 [1286]. A significant reduction of perchlorate to chloride ions occurred on the nickel cathode in the potential region where hydrogen evolution occurs. It was found that the mechanism of this process involves platinum deposited in small amounts on the cathode as a result of oxidation of the platinum anode in the perchloric acid solution. The reduction of perchlorate was accompanied by undesirable oxidation of the nickel cathode, which was attributed to chlorate ions formed in the initial step of perchlorate reduction.

Of five different methods tested for the removal of dissolved perchlorate from water, two methods stood out as the most promising processes: a catalytic dual-

membrane system (described within this publication) and an indirect electrochemical reduction using a titanium electrode [1287].

It was attempted to develop an integrated method for simultaneous removal of perchlorate and chlorate in water by combining ZVI Fe(0) and electrochemical reduction [1288]. However, the use of Fe(0) in electrochemical processes did not produce expected results, as high pH and the presence of hydrogen gas rendered the Fe(0) ineffective for any perchlorate reduction. Electrochemical experiments for perchlorate reduction with nickel or carbon electrodes in the presence of cobalt-based catalysts did result in reaction rate constants that were three to five times higher than those achieved with Fe(0). However, these rates are still too slow for any practical application. Reaction kinetics associated with the electrochemical reduction of chlorate were comparable to that observed with Fe(0), especially at low pH. Surprisingly, bacteria are able to reduce perchlorate in the presence of Fe(0) [1212].

It is known that perchlorate can be reduced to chloride by using electrochemical reduction **or** via bacterial action, but the discovery of perchlorate remediation using bioelectrochemical reduction in a microbial fuel cell is a surprise [1289]. In such a system, not only would perchlorate be destroyed but one would gain electric energy at the same time. Microbial fuel cells (MFCs) may be a suitable method for perchlorate removal. Perchlorate reduction was obtained without the need for exogenous electron shuttles or fixed electrode potentials, achieving a maximum perchlorate removal of 24 mg/L-d and cathodic conversion efficiency of 84%.

Electrodialysis passes water through different membranes while exposing it to an electric field gradient. The electric field separates the perchlorate from the stream of treated water. This produces alternate channels of nearly deionized water (the diluate or dialyzate) and salty water (the concentrate). The diluate is used and the concentrate is discarded. The perchlorate-containing concentrated brine is then appropriately disposed of.

8.9.8 AP Removal via Selective Adsorption on Inorganic Media

Conventional adsorbents used for drinking water purification does not work for perchlorate because the ion is so highly symmetrical and is highly soluble in water. Nevertheless, modified activated carbon (charcoal) has been tested for perchlorate removal from water. In rapid small-scale column tests, cationic surfactant-tailored **activated carbons** (AC's) effectively removed perchlorate to below detection levels for up to 30 times longer than virgin AC. By pre-loading bituminous AC with cationic surfactants, 75 ppb perchlorate was removed for 27000–35000 BVs before the effluent perchlorate rose above 1 ppb. These tests employed a natural groundwater that also contained 30 mg/ LSO_4^{2-} , 26 mg/ LNO_3^- , and other ions [1290–1293]. Tailored GAC can be thermally regenerated (reactivated) and, unlike ion exchange, does not create a new disposal problem with the perchlorate-rich brine that elutes from ion exchange resins during their regeneration. Biological processes do not work well in the ppb

range where activated charcoal can remove the last traces of perchlorate from water (“polishing treatment”).

A total of ten types of commercially available activated carbons were tested for perchlorate adsorption characteristics using pH as the main variable [1294]. The activated carbons were made from different base materials such as wood, bituminous coal, and lignite coal. As such, they possessed different surface characteristics such as specific surface area and surface zero point charge, e.g. pH_{zpc} . Adsorption isotherms were obtained in the pH range of three to ten and for perchlorate concentrations from 0.01 to 1.0 mM. The adsorption isotherms followed the Langmuir type. Surface charge and **not**-specific surface area was the most important factor governing perchlorate removal. All wood-based activated carbons that had a large variation (by a factor of 3) in specific surface area (but very close pH_{zpc}) exhibited similar perchlorate adsorption capacity. On the other hand, the activated carbons with $\text{pH}_{\text{zpc}} > 8$ exhibited higher adsorption capacity than those with low pH_{zpc} of 2–3. This indicated that electrostatic forces are responsible for perchlorate adsorption. However, electrostatics alone failed to explain the better perchlorate removal compared to other anions such as sulfate or phosphate. It was demonstrated that specific chemical interactions between perchlorate and surface functional groups in combination with electrostatic forces were the major mechanism for perchlorate adsorption on activated carbon.

Perchlorate can be removed from contaminated waters using surfactant-modified zeolite [1295].

Mesoporous organosilica materials functionalized with quaternary ammonium ligands were used for the removal of perchlorate anions from aqueous solutions [1296]. The physical and chemical properties of the adsorbent were measured using nitrogen adsorption-desorption measurement, elemental analyses, XRD, and IR spectra. Equilibrium isotherms for the measurement of perchlorate adsorption capacities and kinetic performance were compared to those of organic ion exchange resins.

AP can be co-precipitated with struvite $\text{MgNH}_4\text{PO}_4 \cdot 6\text{H}_2\text{O}$ [1297].

8.9.9 AP Removal via Catalytic Reduction

Of five different methods tested for the removal of perchlorate from water, two methods stood out as the most promising processes: a catalytic dual-membrane system and the indirect electrochemical system using a titanium electrode [1287]. For the former system, it was found that perchlorate was removed completely at a rapid to moderately rapid rate. Ti, Sn, Cr, Mo, Cd, and Pt are the most promising metallic catalysts for the reduction of perchlorate in diluted aqueous solutions.

The reduction of perchlorate in water via dihydrogen under mild conditions can be catalyzed by a catalyst that is prepared by using adsorption of a rhenium(VII) precursor (either ammonium perhenate or methylrhenium trioxide) onto carbon powder containing 5% palladium by weight [1298, 1299]. Under standard batch conditions of room temperature, one bar of hydrogen, and 200 ppm perchlorate (as HClO_4), reduc-

tion proceeded to less than 1 ppm in as little as five hours. Inhibition using chloride was not significant. Optimal reduction activity occurred in acidic solutions (pH ca. 3), and both the rate and extent of reaction decreased at higher values of pH. In its current form, the catalyst might best be used to destroy perchlorate in the acidic regeneration stream from selective ion exchange columns.

An electrodiallytically assisted catalytic membrane system was tested for the reduction of perchlorate in dilute aqueous solutions [1300]. The catalyst support (membrane) was a stainless steel mesh coated with specific monometallic catalysts. A total of 18 different metals covering the first, the second, and the third row of the periodical table were tested. Results indicated that the perchlorate reduction rate decreased in the order: $\text{Cd} > \text{Pt} > \text{Cr} > \text{Mo} > \text{Sc} \gg \text{Rh} > \text{Ru} \sim \text{Sn} > \text{Pd} > \text{V} \sim \text{Ti} > \text{Zn} > \text{Mn} > \text{Ni} > \text{Zr} > \text{Co} > \text{Cu} > \text{Pb}$. Tin was selected for further evaluation in spite of its moderate reaction rate. Results indicated that perchlorate reduction took place rapidly in the concentration range of 2–100 ppm at room temperature and chloride was the major end-product.

The reduction of perchlorate by using dihydrogen gas has advantages in terms of cost, ease in operation, and cleanliness. It was attempted to remove perchlorate ions from dilute solutions using dihydrogen gas assisted by metallic catalysts in a pressurized reactor at room temperature [1301]. Results indicated that perchlorate ions could be reduced to chloride by using molecular hydrogen gas. Among a total of 78 catalyst studied, only 25 showed significant or observable perchlorate reduction. The removal efficiency was about 20% in several hours at an initial perchlorate concentration of 10 ppm in the presence of catalysts. Other metallic catalysts were able to achieve about 90% removal in two weeks at an initial perchlorate concentration of 2 ppm. The most efficient system was the Ti/TiO_2 surface, which had a removal efficiency of better than 90% of the perchlorate ions in about 80 hours, even at an initial very low perchlorate concentration of 1 ppm.

8.9.10 AP Removal via Chemical Reduction

There are only a few reducing agents that will reduce perchlorate to chloride without additional treatment. One of the recommended reducing agents is titanium(III) chloride but it is not exactly the cheapest reducing agent unless one regenerates it continuously via electrolytic reduction (see Section 8.9.7).

Stabilized ZVI nanoparticles can reduce perchlorate in water or ion-exchange brine. Batch kinetic tests revealed that at an iron dosage of 1.8 g/L and at moderately elevated temperatures (90–95 °C), ~90% of perchlorate in both freshwater and in a simulated ion-exchange brine (6% NaCl) was destroyed within seven hours [1302]. An activation energy of 52.6 ± 8.4 kJ/mol was determined for the reaction. Kinetic tests suggested that Cl^{+7} in perchlorate was rapidly reduced to chloride without accumulation of any intermediate species.

Complete (99.9%) perchlorate removal was obtained in a solution containing $[\text{ClO}_4^-] = 1.0$ mM, $[\text{Ti(III)}] = 40$ mM, and $[\beta\text{-alanine}] = 120$ mM after two-and-a-half

hours of reaction at 323 K (50 °C) [1303]. The reaction is influenced by both pH and complex formation. The results revealed that, without β -alanine, the optimal pH was 2.3. The presence of β -alanine significantly increased the reduction rate of perchlorate even at near-neutral pH. This is because β -alanine formed complexes with Ti(III), which greatly improved the total soluble [Ti(III)] in the pH range between 3.5 and 6.

8.10 Other Sources of Perchlorates in the Environment

This chapter discussed sources of perchlorates in the environment other than those attributed to the industrial production of chlorates and perchlorates.

8.10.1 Natural Occurrence of Perchlorate Salts

The natural occurrence of perchlorate salts has already been discussed in Section 1.2. A current theory concerning the origin of naturally occurring perchlorate in the environment focuses on natural atmospheric processes. This theory suggests that chloride, possibly in the form of sodium chloride aerosols from seawater or land-based chloride compounds suspended in the upper atmosphere, reacts with atmospheric ozone to create perchlorate. This process occurs over much of the earth and is analogous to nitrate formation in the atmosphere. In most areas with high precipitation, the perchlorate is extracted from the soil and washed into the ocean. Only in arid areas, such as in the Atacama desert in Chile, can the perchlorate (along with the nitrate) accumulate in noticeable quantities.

Fertilizers continue to contain perchlorates even after the import of Chile saltpeter has ceased [1304, 1305] or the raw saltpeter has been treated to remove some of the perchlorate.

Cases where perchlorate pollution results from non-military and/or natural inputs need to be included in the overall environmental pollution studies [1124, 1306]. In trying to find the source of perchlorate pollution, be that human-made or naturally occurring pollution, analytical tools have been sharpened to trace the origin of perchlorates in the environment [1307]. The formation of perchlorate may be a natural process in the atmosphere [1308].

In the wake of discovering perchlorate ions in the ice of polar caps on Mars, chemists began to take a closer look at the natural occurrence of perchlorate salts on Earth [1309]. Ice and water samples were collected at remote, pristine locations where there was very little chance of industrial pollution. The possibility of naturally occurring perchlorate has only recently received significant attention. Relying primarily on domestic, agricultural, and recreational wells, a network of volunteers was enlisted to help collect 326 groundwater samples from across the coterminous US [13]. Care was taken to avoid known, US EPA-documented sites of perchlorate use or release, as well as perchlorate contamination due to disinfection

using hypochlorite. Using IC-ESI-MS and a $\text{Cl}^{18}\text{O}_4^-$ internal standard, a MDL of $40\text{ ngClO}_4^-/\text{L}$ and a MRL of 120 ng/L was achieved. Of the 326 samples, 147 (45%) were below the MDL, while 42 (13%) were between the MDL and the MRL. Of the 137 samples that could be quantified, most (109) contained 1000 ng/L perchlorates; the remaining 28 samples contained from 1000 to 10400 ng/L . These results support the notion that perchlorate occurs naturally in many groundwaters. However, unusually high concentrations (10000 ng/L) previously reported for the west-central Texas area appear to be anomalous. Perchlorate concentrations were positively correlated with nitrate levels ($P < 0.001$) but not with chloride concentrations.

Gradually the realization begins to emerge that perchlorate ion is more ubiquitous in the natural and unpolluted environment than earlier generations were aware of [14]. Forensic scientists are hunting for evidence of natural versus anthropogenic perchlorate in the environment in an attempt to try and source the cause of perchlorate pollution [1310]. Perchlorates from different origins leave fingerprints behind in the form of their isotope ratios [1311]. The isotope ratios in perchlorates have been measured and they are different for naturally occurring and synthetic perchlorates [330, 1312]. An atmospheric source for this natural occurrence is strongly implicated, and the naturally occurring isotopes of oxygen and chlorine offer considerable promise for unraveling the chemical mechanisms responsible. Perchlorates found in West Texas have isotope ratios that differ from both the Chilean Atacama minerals and from human-made perchlorate. The West Texan perchlorates have formed via a different mechanism from the South American perchlorates or they have been substantially biologically or geochemically altered and re-deposited.

The discovery of perchlorate in soil and ice from several Antarctic Dry Valleys (ADV) where concentrations reach up to $1100\text{ }\mu\text{g/kg}$ was truly surprising [1313]. In the driest ADV, perchlorate correlates with atmospherically deposited nitrate. Far away from any anthropogenic activity, ADV perchlorate provides unambiguous evidence that natural perchlorate is ubiquitous on Earth. The discovery has significant implications for the origin of perchlorate, its global biogeochemical interactions, and possible interactions with polar ice sheets. The results support the hypotheses that perchlorate is produced globally and continuously in the Earth's atmosphere, that it typically accumulates in hyperarid areas, and that it does not build up in oceans or other wet environments most likely because of microbial reduction on a global scale.

A correlation is sought between the detection of perchlorate in the ice caps of Mars and the accumulation of perchlorate in high deserts and the polar regions of Earth.

Isotopic studies indicated that natural perchlorate is produced on Earth in arid environments via the oxidation of chlorine species through pathways involving the ozone or its photochemical products. With this analogy, it was proposed that the arid environment on Mars similarly may have given rise to perchlorate through the action of atmospheric oxidants [1314]. A variety of hypothetical pathways can be proposed including photochemical reactions, electrostatic discharge, and gas-solid reactions. A preliminary study of the means to produce perchlorate was made to shed light on the

origin of Martian perchlorate. Different gas-phase pathways were investigated using a 1-D photochemical model.

Perchlorate ClO_4^- is ubiquitous in the environment. It is produced naturally by atmospheric photochemical reactions. Nitrate-enriched salt deposits of the Atacama Desert (Chile) contain high concentrations of natural ClO_4^- , which have been exported worldwide since the mid-1800s for use in agriculture. The widespread introduction of synthetic and agricultural ClO_4^- into the environment has contaminated numerous municipal water supplies. Stable isotope ratio measurements of Cl and O have been used to discriminate different ClO_4^- sources in the environment. ^{36}Cl measurements were made for further improving the discrimination of ClO_4^- sources [1315]. Groundwater and desert soil samples from southwestern areas of the US contain ClO_4^- , thus being found to have high abundances of ^{36}Cl ($^{36}\text{Cl}/\text{Cl} = 3100 \times 10^{-15}$ to 28800×10^{-15}) compared with those from the Atacama Desert ($^{36}\text{Cl}/\text{Cl} = 0.9 \times 10^{-15}$ to 590×10^{-15}). They were also found to have synthetic ClO_4^- reagents and products ($^{36}\text{Cl}/\text{Cl} = 0.0 \times 10^{-15}$ to 40×10^{-15}). In conjunction with stable Cl and O isotope ratios, ^{36}Cl data provides a clear distinction among three principal ClO_4^- source types in the environment in this geographical area.

There is a widespread presence of naturally occurring perchlorate in the high plains of Texas and New Mexico [1316]. Perchlorate concentrations measured in groundwater from remote locations in the Middle Rio Grande Basin in north-central New Mexico ranged from 0.12 to 1.8 $\mu\text{g}/\text{L}$ [1317].

UV illumination of hypochlorite solutions can lead to the formation of perchlorate. It was demonstrated that perchlorate can be formed via the conversion of chlorine precursors such as aqueous salt solutions of hypochlorite, chlorite, and chlorate exposed to UV radiation [1318]. Other experiments subjected such solutions to electric discharges. These also formed perchlorate.

Ozonization of drinking water has been widely advertised as a safer method compared to chlorination in that it avoids formation of halogenated organic compounds (chloroform) in drinking water. Only a few people have recognized that there is a potential of inadvertently forming perchlorate by ozonization of chloride ions in the incoming water [1319]. The yields and rates of ClO_4^- production from O_3 -mediated oxidation of Cl^- , OCl^- , ClO_2^- , ClO_3^- , and ClO_2 were measured as a function of reactant (O_3 and ClO_x^-) concentrations and pH [1320]. The comparative rate and efficiency of ClO_4^- production is generally greater for higher oxidation states of Cl (2.7 to 0.5% for $\text{ClO}_2^-/\text{ClO}_2$ and 0.02 to 0.005% for OCl^-/HOCl oxidation) with the notable exception of ClO_3^- , which does not react with O_3 . The very slow rate of ClO_4^- production from Cl^- ($20 \times 10^{-9} \text{ mM min}^{-1}$) even at elevated O_3 and Cl^- concentrations implies negligible potential for inadvertent ClO_4^- formation in process units of water/wastewater treatment systems that use ozonization for treatment. ClO_2 and higher oxy-chlorine radicals/intermediates (e.g., Cl_2O_6) may play a role in perchlorate formation. A similar process may take place with aerosol-borne chloride in the upper atmosphere under the influence of ozone and UV light. This may be responsible for the natural production of perchlorates.

Chlorine is known to play an important role in ozone layer chemistry, including the feared ozone destruction and formation of ozone layer holes. The same sequences of reaction can generate perchlorate, which is the most stable end-product in any series of reactions involving chlorine-oxygen species.

The frequency of detection of perchlorate in groundwater and drinking water supplies has been steadily increasing since its initial identification as a chemical of concern in 1997, however, perchlorate has also been detected in many locations in the groundwater away from any industrial pollution and human impacts (like agriculture and fertilizer). The search is on for alternative causes of widespread low perchlorate concentrations found in groundwater [1321].

Perchlorate stable isotope data ($\delta^{37}\text{Cl}$, $\delta^{18}\text{O}$, and $\Delta^{17}\text{O}$), along with other supporting chemical and isotopic environmental tracer data, were used to document groundwater ClO_4^- contamination sources and history in parts of Long Island, New York [1322]. Sampled groundwaters were oxidic and ClO_4^- were apparently not affected by biodegradation within the aquifers. Synthetic, as opposed to natural, ClO_4^- was indicated by the isotopic method in groundwater near an ordnance disposal site at a former missile base. Atacama ClO_4^- was indicated in agricultural and urbanizing areas in groundwaters with apparent ages 20 years. In an agricultural area, ClO_4^- concentrations and $\text{ClO}_4^-/\text{NO}_3^-$ ratios increased with groundwater age, possibly because of the decreasing application rates of Atacama NO_3^- fertilizers and/or decreasing ClO_4^- concentrations in Atacama NO_3^- fertilizers in recent years. Groundwater ClO_4^- with distinctive isotopic composition was a sensitive indicator of past Atacama NO_3^- fertilizer use on Long Island and may be common in other areas that received NO_3^- fertilizers from the late nineteenth century through to the twentieth century.

Stable isotope studies of nitrate deposits in various parts of the world have supported the atmospheric origin of the nitrate. The processes that form and accumulate natural nitrate can provide clues as to the origin and mechanisms of formation of naturally occurring perchlorate. Chlorine participates in many photochemical reactions in the atmosphere and global photochemical perchlorate formation in the atmosphere has been demonstrated. Thus, the question is not which areas are under perchlorate-containing rain but which geological and climate conditions allow perchlorate in some areas to be concentrated to achieve environmentally or toxicologically significant concentrations [1323]. The area where the highest amount of nitrate and perchlorate has accumulated is the Atacama desert in Chile. Isotope studies now confirmed the atmospheric origin of these anions.

Natural perchlorate is believed to be of atmospheric origin. However, until recently, no systematic study had been conducted to evaluate perchlorate deposition rate and possible seasonal or spatial variations. Perchlorate concentrations in weekly composite wet deposition samples acquired through the National Atmospheric Deposition Program from 26 sites across the continental US, Alaska, and Puerto Rico for a period of one to three years were analyzed using very sensitive analytical meth-

ods [1324]. Perchlorate concentrations varied from 5 ng/L to a high of 102 ng/L with a mean of 14.1 ± 13.5 ng/L for the 1578 total samples. The annual perchlorate flux by site ranged from a low of 12.5 (TX) to 157 mg ha⁻¹ yr⁻¹ (NE) and averaged 65 ± 30 mg ha⁻¹ yr⁻¹ for all sites. Perchlorate concentrations and flux in wet deposition were generally highest between May to August, declining to lows between December-February, which seems to correlate with sunshine hours in the northern hemisphere. Average annual perchlorate flux was correlated ($r > 0.5$; $p < 0.001$) with Ca²⁺, K⁺, NH₄⁺, NO₃⁻, Cl⁻, and SO₄²⁻ measured at the same time. Wet deposition rate of ClO₄⁻ in the conterminous US (excluding Alaska, Hawaii, and Puerto Rico) while diffuse, represents a potential annual net mass flux of 51000 kg/yr. This value is comparable to the estimated annual environmental releases from other known ClO₄⁻ sources.

The isotopic composition and stable isotope ratios of natural ClO₄⁻ indigenous to the southwestern areas of the US were measured in ClO₄⁻ ($\delta^{18}\text{O}$, $\Delta^{17}\text{O}$, $\delta^{37}\text{Cl}$) and associated NO₃⁻ ($\delta^{18}\text{O}$, $\Delta^{17}\text{O}$, $\delta^{15}\text{N}$) in groundwater from the southern High Plains of Texas and New Mexico and the Middle Rio Grande Basin in New Mexico (from unsaturated subsoil in the southern High Plains of Texas and from NO₃⁻-rich surface caliche deposits near Death Valley, California) [1325]. The data indicated that natural ClO₄⁻ in the southwestern areas of the US has a wide range of isotopic compositions that are distinctly different from those reported previously for natural ClO₄⁻ from the Atacama Desert of Chile as well as all known synthetic ClO₄⁻. ClO₄⁻ in Death Valley caliche has a range of high $\Delta^{17}\text{O}$ values (+8.6 to +18.4‰), overlapping and extending the Atacama range, indicating at least partial atmospheric formation via reaction with the ozone. However, the Death Valley $\delta^{37}\text{Cl}$ values (-3.1 to -0.8‰) and $\delta^{18}\text{O}$ values (+2.9 to +26.1‰) are higher than those of Atacama ClO₄⁻. In contrast, ClO₄⁻ from western Texas and New Mexico has much lower $\Delta^{17}\text{O}$ (+0.3 to +1.3‰), with relatively high $\delta^{37}\text{Cl}$ (+3.4 to +5.1‰) and $\delta^{18}\text{O}$ (+0.5 to +4.8‰), indicating either that this material was not primarily generated with O₃ as a reactant or that the ClO₄⁻ was affected by post-depositional O isotope exchange. High $\Delta^{17}\text{O}$ values in ClO₄⁻ (Atacama and Death Valley) are associated with high $\Delta^{17}\text{O}$ values in NO₃⁻, indicating that both compounds preserve characteristics of O₃-related atmospheric production in hyper-arid settings, whereas both compounds have low $\Delta^{17}\text{O}$ values in less arid settings. This study provides important new constraints for identifying natural sources of ClO₄⁻ in different environments by using multi-component isotopic characteristics. It also presents the possibility for divergent ClO₄⁻ formation mechanisms and (or) ClO₄⁻ isotopic exchange in biologically active environments.

Just when it seemed that isotope ratio measurement was a sure shot method to identify perchlorates from different sources, a new complication arose from the discovery that bioreduction of perchlorates proceeds at different rates depending on the isotopic makeup of the perchlorate ion. Thus, the perchlorate chlorine or oxygen isotope ratio in the inflow and outflow of a bioreactor or an underground bioreduction zone would be different depending on how long the reduction has been going on. Isotopic ratios may also be useful for identifying the extent of biodegradation of per-

chlorate, which is critical for assessing the natural attenuation of this contaminant in groundwater.

Because bacteria typically fractionate isotopes during biodegradation, stable isotope analysis is increasingly used to distinguish this process from transport or mixing-related decreases in contaminant concentrations. However, for this technique to be useful in the field to monitor bioremediation progress, isotope fractionation must be quantified under relevant environmental conditions. An *in-situ* experiment was performed in a shallow alluvial aquifer in Maryland to quantify the fractionation of stable isotopes in perchlorate (Cl and O) and nitrate (N and O) during biodegradation. During this field experiment, perchlorate concentrations decreased by 78% and nitrate concentrations decreased by 82% during the initial 8.6 hours after the injection [1326]. The observed ratio of fractionation effects of O and Cl isotopes in perchlorate ($\epsilon^{18}\text{O}/\epsilon^{37}\text{Cl}$) was 2.6, which was similar to that observed in the laboratory using pure cultures (2.5). Denitrification by indigenous bacteria fractionated O and N isotopes in nitrate at a ratio of ~ 0.8 ($\epsilon^{18}\text{O}/\epsilon^{15}\text{N}$), which was within the range of values reported previously for denitrification. However, the magnitudes of the individual apparent *in-situ* isotope fractionation effects for perchlorate and nitrate were appreciably smaller than those reported in homogeneous closed systems (0.2 to 0.6 times), even after adjustments for dilution were made. These results indicated that (1) isotope fractionation factor ratios ($\epsilon^{18}\text{O}/\epsilon^{37}\text{Cl}$, $\epsilon^{18}\text{O}/\epsilon^{15}\text{N}$) derived from homogeneous laboratory systems (e.g., pure culture studies) can be used qualitatively to confirm the occurrence of *in-situ* biodegradation of both perchlorate and nitrate, however, (2) the magnitudes of the individual apparent ϵ values cannot be used quantitatively to estimate the *in-situ* extent of biodegradation of either anion while the plume migrates through subterranean strata.

Measurements of stable isotope ratios of light elements (H, C, N, O, S, Cl) can often be used to distinguish biodegradation of organic and inorganic molecules from abiotic loss mechanisms such as adsorption, dispersion, or volatilization because of the relatively large kinetic isotope effects accompanying biodegradation. Chlorine isotope fractionation during perchlorate biodegradation via a common perchlorate-reducing bacterium, *Dechlorosoma suillum*, initially isolated from a perchlorate-contaminated groundwater source in southern California, was measured [1327]. The values of the chlorine isotopic fractionation factor α derived from two microcosm experiments were $\alpha = 0.9834 \pm 0.0001$ ($R^2 = 0.9999$) and $\alpha = 0.9871 \pm 0.0008$ ($R^2 = 0.9832$). These α values indicated that the rate of the $^{35}\text{ClO}_4$ reduction is 1.3–1.7% faster than that of the $^{37}\text{ClO}_4$ reduction. This relatively large kinetic isotope effect indicates that chlorine isotope analysis provides a sensitive technique by which to monitor the progress of *in-situ* bioremediation of perchlorate in groundwater.

The kinetic isotopic fractionations of O and Cl during perchlorate biodegradation must be known as a function of environmental variables such as temperature and bacterial species. A laboratory study was performed in which the O and Cl isotope ratios of perchlorate were monitored as a function of degradation by two separate bacte-

rial strains (*Azospira suillum* JPLRND and *Dechlorospirillum* sp. FBR2) at 283 and 295 K (10 °C and 22 °C) with acetate as the electron donor [1328]. Perchlorate was completely reduced by both strains within 280 hours at 22 °C and 615 hours at 10 °C. Measured values of isotopic fractionation factors were $\epsilon^{18}\text{O} = -36.6$ to -29.0‰ and $\epsilon^{37}\text{Cl} = -14.5$ to -11.5‰ , and these showed no apparent systematic variations with either temperature or bacterial strain. The fractionation factor ratio $\epsilon^{18}\text{O}/\epsilon^{37}\text{Cl}$ was nearly invariant in all experiments at 2.50 ± 0.04 . These data indicate that isotope ratio analysis will be useful for documenting perchlorate biodegradation in soils and groundwater. The establishment of a microbial fractionation factor ratio ($\epsilon^{18}\text{O}/\epsilon^{37}\text{Cl}$) also has significant implications for forensic studies (see [1329] also).

8.11 Pyrotechnical Sources of Perchlorates

Perchlorates and chlorates are widely used in display fireworks pyrotechnics and road flares. The combustion of these formulations is not 100% efficient. In the case of fireworks, not all stars (little cubes or balls of a pyrotechnic burning in different colors) ignite when the shell bursts and some fall to the ground unburnt.

It helps to assess the AP contamination problem by comparing it to other sources of perchlorates (mainly potassium perchlorate) in other applications such as road flares and fireworks [278]. Road flares contain 5–7% potassium perchlorate but most of it is consumed when the flare is burned as intended. Residual perchlorate in commercial products ranged from 0.094 mg perchlorate per gram material (flares) to 0.012 mg perchlorate per gram material (AN emulsion explosives). Laboratory-prepared rocket propellant formulations generated 0.014 mg of perchlorate residue per gram of material [1330]. The slag left behind by road flares was analyzed and found to contain residual perchlorates [1331].

If fireworks execute as intended, most of the perchlorate should be consumed by the time the ashes rain down on the footprint area below a fireworks display. As any pyromaniac who is seen in the early morning hours of July 5th scrounging around fireworks launch sites knows, not all the stars ignite and a certain percentage falls to the ground unburned, carrying some perchlorate with them [1332]. Studies have shown that natural perchlorate may be an important component to the general population exposure. These studies indicate that natural perchlorate is likely precipitated by atmospheric deposition. Perchlorate concentration of total (dry + wet) deposition is relatively unstudied, yet these measurements will aid in understanding natural levels in the environment. The total deposition was sampled monthly at six sites in Suffolk County, Long Island, and New York from 30 November 2005 until 5 July 2007. The mean perchlorate concentration was 0.21 ± 0.04 (standard error) $\mu\text{g/L}$ with a maximum value of $2.78 \mu\text{g/L}$. There was an 18-fold increase above the mean concentration in the July 2006 and July 2007 samples. It appears that this increase in perchlorates in the total deposition is associated with July 4th fireworks in the US.

8.11.1 Residual Perchlorates in Rocket Exhaust

For the normal operation of a solid-propellant rocket motor with an AP-based propellant, the combustion should be complete and there should be no detectable perchlorate in the exhaust.

At the very high operating temperature of rocket motors and in the immediate vicinity of combustible fuels and metals, all perchlorate would be converted to chloride. In a properly operating rocket, there should be no undecomposed perchlorate (or chlorate) in the exhaust, except toward the end when combustion has ceased, chamber pressure has dropped below the lower pressure limit, and when slivers of unburnt propellant are smoldering in the hot casing. Solid rocket boosters with thrust termination ports may contain substantial amounts of unburnt propellant at the time they impact the ocean if the thrust termination port was commanded open after the necessary ΔV was achieved.

Normal Operation

Analytical methods for the analysis of unburnt rocket propellant reactants were described in Section 4.2.4.12.

Assessment of Perchlorate Releases in Launch Operations

Static firings of AIM-7 rocket motors were conducted to measure the environmental dispersion of unburnt AP during normal operating conditions [1333]. Fifteen MK-58 motors were statically fired on a test bench to measure the residues that were expelled during combustion and collected on aluminum witness plates and aqueous traps located in the exhaust plume area. Perchlorate was detected in most of the samples collected due to the use of a very sensitive analytical method. The results obtained were consistent and reproducible. It was estimated that only 2mg of perchlorate was deposited per MK-58 motor. Considering the motor's flight range, it was concluded that their use in live-fire training does not contribute to the accumulation of perchlorate in the environment.

Launch Mishaps

The destruct charge was initiated on command after one of the boosters of a TITAN-IIIC developed a problem during launch in 1986 resulting in a shower of burning chunks of AP-containing composite propellant raining down on the landscape. A failure of a Titan-III at Vandenberg AFB on 18 April 1986, and the activation of the destruct system command released a spectacular fireworks of burning propellant fragments falling onto the coastline and into the ocean. As part of the anti-ballistic missile defense development testing, intentional intercepts of missiles during the launch phase will release unburnt propellant into the environment.

A study sponsored by the Air Force Space Missile Systems Center's Environmental Management Branch looked at the "what if?" situation after unburnt propellant from an aborted solid rocket launch is scattered over estuaries and seashore adjacent to

a launch site. Laboratory studies were conducted to determine the rates at which perchlorate is released from perchlorate-containing solid propellants and the influence of temperature and salinity on the rate of perchlorate release [1334, 1335]. The perchlorate leaching rates depend on the type of binder the AP is encased with in solid propellants. Perchlorate release rates from CTPB, HTPB, PBAN, and polyurethane (PU) solid propellants were determined in freshwater and seawater at temperatures between 278 and 303 K. HTPB is used in more recent SRMs such as Delta-IV, Atlas-V, Pegasus, and Titan-IV. PBAN was the binder used in STS SRBs and Titan-III. CTPB and PU are used in Minuteman stages and by the Quick Reaction Launch Vehicles (Taurus). Perchlorate release rates were expressed as diffusion coefficients. The diffusion coefficients for all propellant types and conditions tested were in the range of 3.6×10^{-12} to $1.1 \times 10^{-13} \text{ m}^2/\text{s}$. Diffusion coefficients were proportional to temperature and inversely proportional to salinity. The report also contains an analysis of water samples (for metals and other contaminants) in which solid propellant samples were immersed for 11 months. Soaked propellant samples assumed a sponge-like consistency.

The perchlorate leaching rates measured on laboratory samples were then combined with a launch vehicle failure model that calculates the sizes of propellant fragments and the debris stray field depending on the height, azimuth, and velocity at the time of the accident when the destruct mechanism was activated [1336].

9 Handling of Ammonium Perchlorate

A person preparing to handle larger quantities of AP or a person in charge of training new personnel about the safe handling of AP (or any other chemical) would typically start with consulting the MSDS supplied with the material from a vendor. Unfortunately, the MSDSs that were located during a recent online search were invariably of very poor quality and required updating and correcting. There are some MSDSs posted online that are outright misleading, incorrect, incomplete, and therefore useless, e.g.:

- http://www.sciencelab.com/xMSDS-Ammonium_perchlorate-9922929 (accessed 1 October 2017)
- <http://www.gfschemicals.com/msds/3MSDS.pdf> (accessed 1 October 2017)

9.1 Transportation of Ammonium Perchlorate

The transportation hazard classification for AP is Oxidizer Classification 5.1. The UN shipping identification number is UN1442. This classification was based on detonability tests conducted in accordance with TB700-2. This classification fails to limit the particle size, although it is now known that finely ground AP is detonable and should not be shipped under an Oxidizer designation.

In the wake of the incident at the PEPCON plant on 4 May 1988, the transportation classification was re-examined and subjected to a critical re-examination.

Nominal 200- μm particle size propellant grade AP in 114-L (30 gallons) DOT specification 37A-350 steel drums with bolted ring closures containing approximately 114 kg (250 lb) of material had successfully undergone shipping container safety testing in 1982 [1337]. However, the same material in 208-L (55 gallons) DOT specification 17H steel drums containing 227 kg (500 lb) of AP and aluminum bins conforming to requirements of DOT Specification 56, containing from 2045 to 2270 kg (4500 to 5000 lb) of AP, both of which were involved in the PEPCON incident, had not been subjected to the same testing. These larger containers had been approved by analogy with AP behavior in the 114-L (30 gallons) steel drums.

9.2 Storage of Ammonium Perchlorate

Under the recommendations issued by the National Fire Protection Association's (NFPA) Code for the Storage of Liquid and Solid Oxidizers [1338], coarse AP is ranked as a Class 4 oxidizer (the oxidizer class with the highest hazard rating). As such, the requirements (number and spacing of sprinklers, separation from nearest important structure, the need to use non-combustible materials of construction for storage buildings, storage bins) must be met for storing any amount of AP in excess of 4.5 kg (10 lb) in weight in one location. Finely pulverized AP with particle sizes below 15 μm is classified as an explosive.

9.3 Transportation and Hazard Classification Tests of Ammonium Perchlorate

A series of hazard classification tests were conducted on AP (nominal 200 μm size) packaged in 113.6 liters (30 gallons) DOT 37A-350, 20-gage steel drums with bolted ring closures, with each containing approximately 113.4 kg (250 lb) of material [1337]. The dimensions of the drums were 0.74 m high by 0.49 m in diameter with 0.8 mm thick walls. [Note: This is a heavier gage (20 gages versus 24 gages) drum than required for US shipment of this material.] The material was packaged inside the drum in two electrically conductive PE bags with approximately 4.5 kg (10 lb) of desiccant placed atop the AP inside the inner bag. The gross weight of the drums and contents averaged 119.5 kg (264 lb) and moisture content was approximately 0.007 mass-%. All tests were conducted in accordance with INTERREG, Transport of Dangerous Goods, 1981 Edition (<https://www.interregeurope.eu/>). A first series of type 6a single package tests were conducted on single drums of AP, each confined in all directions by 1 m (3.28 ft) of sandbags. In this test, a drum containing AP was placed on a steel witness plate (0.81 m $\times$ 0.81 m $\times$ 12.7 mm thick = 2.67 ft. by 2.67 ft. by 0.5 in.) at ground level. In all tests, the material thermally decomposed. There was no explosion, no overpressure

detected, and no rupture, splitting or fragmenting of the drum. In a second series of type 6a single package tests on single drums of AP confined in the same manner as in the first type 6a series, the initiation source was a No. 8 blasting cap. In this series, the AP also thermally decomposed and there was no explosion, no overpressure detected, and no rupture, splitting, or fragmenting of the drums. For control and information purposes, a single drum of AP was tested unconfined using an S94 squib and 56.7 g (2 oz) of FFF black powder as the ignition source. The ignition of the black powder caused the drum lid to pop off and ejected approximately one-third of the AP from the drum. The AP did not react or thermally decompose and there was no damage to the drum. The series of 6b stack tests were not conducted due to the lack of any explosive effect in either of the type 6a, single package test series. This is in accordance with paragraph 4.5.5 of the INTERREG standard. Based upon the interpretation of test results as outlined, AP nominal 200-micron particle size in 113.4 kg (250 lb) quantities in steel shipping drums does not meet the requirements for a Class I material.

Based upon laboratory test results, the West German representative to the UN Committee on the Transportation of Dangerous Goods recommended that AP of all particle sizes be classified as a Class 1.1 explosive [1339]. If this recommendation had been adopted, it would have had a drastic effect on the transportation of AP with commercial transports and military agencies. Under regulations that came into effect in 1982, only AP with a particle size less than 45 μm was considered a Class 1.1 explosive (the latest DARCOM regulation specifies 15 μm or less). Above 45 μm , AP was classified as a 5.1 oxidizer. In order to resolve this difference, a plan for conducting UN Test Series 6 for packaged AP, 200 μm size in 113-L, 113-kg (30-gallon, 250-lb) steel drums was developed in co-operation with the Joint Army Navy NASA Air Force (JANNAF) Inter-agency Propulsion Committee and US Army Development and Readiness Command (DARCOM) Safety Office.

As a result of challenges to the transportation hazard classification of AP by certain members of the United Nations' Committee on the Transport of Dangerous Goods, a test program was conducted by the US. Data was forwarded to the UN to retain a Class 5.1 designation (oxidizer) for AP, which is shipped internationally [1340]. As a follow-on to the initial team effort to conduct AP tests, the Chemical Propulsion Information Analysis Center (CPIAC) has researched existing data and compiled a matrix which catalogs test parameters and findings. These may be useful should questions of a similar nature arise in the future. Further to this, a collection of test protocols have been reviewed by a subgroup of the same UN Committee of Experts in an attempt to standardize test methods for energetic materials of all types.

Following the May 1988 explosion at Henderson, NV, some of the transportation hazard classification tests were repeated [1341]. The incident at PEPCON, Nevada, raised concern over the transportation and storage safety of 208L (55 gallons) DOT Specification 17H steel drums containing 227 kg (500 lbs) of AP and aluminum bins containing 2045 to 2770 kg (4500 to 5000 lbs) net weight AP meeting requirements of DOT Specification 56. As a result, these containers were subjected to a series

of additional transportation certification tests. Test procedures were patterned after the 1986 issue of the United Nations publication, *Recommendations on the Transport of Dangerous Goods: Test and Criteria*, (ST/SG/AC.10/11) Test Series 6, Section 41 through 44. The results of the tests for both drums and bins containing nominal 200- μ m particle size propellant grade AP confirmed the appropriate US DOT classification of AP as an oxidizer (ID number UN1442).

9.4 Recycling of Ammonium Perchlorate

Instead of open burning of AP-based solid propellants in aged missiles at the end of their useful life, water-jet cutting, and dissolving (“hogging out”) of AP-based propellants is a safer and environmentally more acceptable method of demilitarization. This provides an opportunity to recycle the AP that has been leached from the propellant.

There will be detailed chapters on the demilitarization of solid propellants in future volumes on solid propellants. This will include several AP-based propellants but will not necessarily involve recycling and re-using the oxidizer. The current chapter concentrates on recycling and re-using the washed-out AP oxidizer.

Liquid ammonia has been evaluated as a solvent system for the recovery of AP and other components from composite propellants

A solid-propellant ingredient reclamation pilot plant has been established at the Strategic Operations of Thiokol Corporation, located in Brigham City, Utah [1342]. The plant produced AP wet cake (95% AP, 5% water) for reprocessing at AP vendors. AP was extracted from two standard propellant binder systems (PBAN and HTPB as binders). Analytical work conducted at Thiokol indicated that the vendor-recrystallized AP meets Space Shuttle propellant specification requirements. One-, 5-, and 600-gallon propellant mixes were processed with the recrystallized AP. Processing, casting, curing, ballistic, mechanical, and safety properties were evaluated and compared to propellant made with fresh AP. Phillips Laboratory static-test-fired 70-lb_f and 800-lb_f Ballistic Test Evaluation Motors (BATES). The data indicated that propellant processed with reclaimed AP had nominal properties.

AP reclaimed using the water dissolving technique developed by the Thiokol Corporation was compared to two types of fresh AP in a PBAN propellant formulation [1343]. The reclaimed AP was directly substituted for the virgin AP. Side-by-side analyses of the reclaimed and virgin AP samples were performed to identify the chemical and physical properties of each. Variances for the propellant mixes were established in the areas of processing, mechanics, and ballistics. The PBAN and CTPB propellant formulations were scaled up to the 30-gallon mix size, and 70-lb BATES were cast and fired. Results revealed that reclaimed AP has the potential to be substituted for fresh material without any undue effects.

Titan-IV solid-propellant rocket motor segments were processed to recover the AP for reuse [1344]. Water used during processing was recycled in a closed-loop cycle

to save treatment costs and minimize the total volume required. The closed-loop AP recovery technology was first demonstrated during 1996 on a Minuteman Stage I solid-propellant rocket motor. After this technology was developed, byproducts from washout of solid propellant rocket motors were disposed of by open burning. The process used by Thiokol on Titan-IV solid propellant rocket motors recovered the AP from the washout refuse, thus eliminating the burn disposal. A Titan-IV rocket motor center segment was approximately ten feet in diameter and ten feet long. The weight was over 90000 lbs, which includes 70000 lbs attributed to the Class 1.3 solid propellant. Removal of propellant by hydromining and processing the removed propellant to recover AP was safely done and AP was recovered from the washed-out propellant.

Another system was designed to remove dissolved AP from the washout water by concentrating and precipitating the AP in an evaporator [1345]. The evaporator processes the 10% AP solution at 22 gallons/min and was designed to match the production rate of Thiokol's propellant washout facility. The AP slurry produced in the evaporator was dewatered by a centrifuge and automatically loaded into 55-gallon drums for reuse at the rate of 1000 lbm/h. Part of the evaporator system included equipment that sized the AP crystals. The recovered AP was 99% pure and could be reused in manufacturing new propellant. The end products of the process were crystalline AP and distilled water. The distilled water was recycled and returned to the propellant removal facility for reuse in washing out more propellant. As of the year 2000, the facility had been operating for approximately one year and had recovered 830000 pounds of AP and has evaporated 988000 gallons of AP washout water.

Among others, several (12 filament-wound segments and four unusable steel segments) Space Shuttle rocket motor segments (12 feet in diameter, 30 feet long, and over 300000 pounds each) have been washed out [1346]. The facility used high-pressure water to remove the propellant from the segments. Propellant removal rates of over 3000 lbm/h have been demonstrated. During the washout process, the majority of the AP in the propellant is leached into the process water. This water is then processed to reclaim the AP.

In addition to using water as the solvent for AP extraction from decommissioned propellant, ionic liquids have been evaluated as solvents that can serve at the same time as electrolytes for the destruction of perchlorate ions via electrochemical reduction [1347]. The electrochemical degradation of perchlorate ions and their conversion to harmless chloride during electrolysis was studied using IR and ^{35}Cl NMR spectroscopies.

Leaching AP from composite solid propellants is an internal diffusion process that is controlled by diffusion of water and AP in the propellants and the leaching-rate equation is a first-order dynamic equation [1348]. Surface topography of propellant samples before and after extracting AP with water was observed by using SEM [1349]. Results revealed that extraction time, extraction temperature, and the thickness of the specimen greatly affect the effectiveness of AP extraction while stirring speed had

little effect. The optimum extraction conditions were: An extraction time of six hours and extraction temperature of 353 K (80 °C), a mass ratio of raw materials to solution of 1:5, and a 2 mm thickness of shredded specimens. The extracting water was replaced twice. The AP recovery rate was 87%.

9.5 Disposal of Ammonium Perchlorate

The disposal of AP in aqueous solutions from propellant manufacturing processes and polluted groundwater sources has already been discussed in Section 8.9. The demilitarization of AP-based propellants and explosives poses a different problem.

Twenty years ago, a book like the one at hand would have dealt only with the industrial disposal of out-of-date propellant and of AP production waste streams. For the aged propellant, open-air burning would still have been listed as a disposal option. There are only very few facilities that can still perform open-air burning. In the meantime, the spread of perchlorate pollution has shifted the emphasis from the production wastes to those wastes that have already entered and spread throughout the environment. Consequently, environmental pollution clean-up methods have received stronger emphasis, a fact that is reflected by the number of publications cited in this book. Although the concentrations vary over several orders of magnitude, basically the same methods can be used for the destruction of perchlorate in aquifers, wastewater impoundments, and rocket motor washout effluents, including biochemical methods.

There are only relatively few publications that deal strictly with the controlled disposal of AP. After assuring the non-toxicity of AP against micro-organisms performing municipal sewage treatment, the biological reduction of AP to form inoffensive chemical species (N_2 , H_2O , Cl^-) was demonstrated using a two-step process with two ponds (lagoons). In the first one, under oxic conditions, the NH_4 was oxidized to NO_2^- and NO_3^- (nitrification). In the second the oxidized species were reduced to N_2 , H_2O , Cl^- under anoxic conditions. The overall process required carefully selected operating conditions and the addition of some nutrients [1350, 1351].

Other options for the disposal of AP production brines are concentration in solar ponds for solid-state landfill disposal or dilution with seawater and pumping it out to sea [1352].

9.6 Accident History of Ammonium Perchlorate

9.6.1 AP Production Accidents

Detailed descriptions of events leading to accidents and post-accident cause-and-effect analyses were published after the May 1988 AP explosion at PEPCON Henderson, NV [1353–1355]. The fire quickly spread through most of the facility by means of thermal radiation, firebrands, and a continuous source of fuel adjacent

to a powerful oxidizer [1356]. Two large explosions occurred during the fire, each on the order of a few hundred tons energy equivalents of TNT, claiming two lives, injuring 372 people, and damaging plant buildings as well as many buildings in nearby residential areas. During the early stages of the plant fire, a television tower maintenance crew atop a nearby mountain noticed the event and recorded most of it on videotape. The video record is unusual, spectacular, and a rare opportunity in fire/explosion investigation. It shows details of the rapid plant fire spread sequence, much of which occurred too quickly to be accurately recorded by any other means (Figure 49).

Figure 49: May 1988 AP explosion at PEPCON Henderson, NV. (From Wikipedia; AP-49-Henderson-AP-1988.jpg from https://en.wikipedia.org/wiki/PEPCON_disaster, Screenshot from a video taken by Dennis Todd, reuse licensed under CC BY 2.0.)

After the accident, an on-site accident investigation was conducted to determine the number and magnitude of explosions that occurred [1357]. Included in the investigation was the measurement of damage to many metal structures and objects throughout the plant. The locations of explosion centers were determined from craters and the direction of structural deformation. The deformation and standoff data were the basis for the calculation of blast yield for several explosions which occurred during the accident sequence.

Damages caused were surveyed and interpreted for their estimated causative air blast overpressures [1358]. Results were widely scattered by uncertainty in structural (primarily window glass) response as well as weather effects, but the total pattern of estimated overpressures versus distances generally agreed with a $1\text{ kt} = 1\text{ Gg}$ NE assumption for the airburst source strength. This would correspond to a 227 Mg HE surface burst. Since approximately 1.36 Gg AP were destroyed in the area of the largest single explosion, an HE explosive equivalence for AP appears to be about 1/6. Considering the yield-scaled response of overpressures to yield, there is no significant difference with an independent yield estimate of 454 Mg HE, made from close-in blast effects on easy-to-model structural elements (steel beams).

In the wake of this disastrous AP explosion, there was insufficient AP in storage to cover the production loss and to keep the US space program going while the cause of the accident was investigated and the plant was being rebuilt. For several decades, the US had the luxury of several AP producers. As a result of the temporary AP shortage in the US, the remaining AP had to be allocated to high-priority programs [1359].

American Pacific gained sole control of the industry in 1998 when Kerr-McGee sold its perchlorate operations to AMPAC.

9.6.2 AP Recycling Accidents

During the development of a propellant demilitarization and AP recycling process at Amtec, a mixture of AP and butanol ignited and exploded, killing two of the operators, Jim Hawke and Jerry Grimes.

On 20 February 2011, Major General Jim Rogers, Commanding General of U.S. Army Aviation and Missile Command (AMCOM) and Redstone Arsenal, announced the results of the investigation into the 5 May 2010 explosion at Building 7352, Test Area 10, on Redstone Arsenal. The investigation determined that the cause of the explosion was Amtec's operation of a particular type of decanter centrifuge to process potentially explosive materials. The investigation found that the deaths were the result of Amtec personnel conducting decanter centrifuge tests involving potentially explosive materials as an attended operation instead of running the tests remotely. Amtec was responsible for safety within Building 7352 pertaining to its operations. Amtec personnel selected, purchased, installed, and independently operated the decanter centrifuge. The investigation concluded that this type of centrifuge was unsuitable and unsafe for processing explosives. Responsible Amtec personnel did not develop safety procedures specific to the use of the centrifuge and exercised poor safety discipline. Amtec employees were working on demilitarization operations that involved AP. The goal was to develop the optimal process for achieving reclaimed dry AP at maximum recovery. To separate the AP, Amtec was using *n*-butanol as a solvent to dissolve away impurities from the AP. AP and *n*-butanol were mixed together to form a slurry. Amtec personnel were using a decanter centrifuge, which spins at high speed to remove the *n*-butanol from the AP and to dry the AP. AP wet with *n*-butanol has high chemical energy and can be explosive. During the process on 5 May 2010, friction from rotating parts inside the decanter centrifuge generated enough heat to cause a mixture of AP and *n*-butanol to ignite. The flame led to an explosion within the decanter centrifuge causing fragmentation and ultimately producing an intense fireball that engulfed personnel present in the building. The full press release may be found online [1360].

10 Explosive and Fire Hazards of Ammonium Perchlorate

The explosive properties and sensitivity of AP were determined by measuring shock and high-velocity impact sensitivities, minimum boosting requirements, the critical diameter for sustained propagation in unconfined charges, and by measuring "sensitivity" (air gap propagation or sympathetic detonation) determined in unconfined and barrel size charges [1361]. Detonation velocities and detonation pressures were also measured.

10.1 Drop Weight Impact Sensitivity of Ammonium Perchlorate

10.1.1 Drop Weight Impact Sensitivity of AP by Itself

The drop weight impact sensitivity of AP depends on the crystal size and on the humidity content. The drop weight sensitivity of AP can be reduced by coating or co-crystallizing with a few percent of ammonium tetrafluoroborate, which is isomorphous with AP and can form a solid solution at the interface [1362]. The 50% point of untreated AP was at 40 cm. By coating with 6, 10, or 20 mass.-% NH_4BF_4 , the sensitivity decreased and the drop height went up to 73, 77, or 82 cm. NH_4BF_4 has also been tested as an inhibitor in the thermal decomposition of AP.

The drop weight impact initiation of AP is related to the mechanical failure of the crystal creating hot spots. At the hot spot, the local temperature is limited by the incipient melting of the rapidly heated crystal. An investigation of the dependence of the pressure at which crystal fracture or explosion occurs as a function of the sample thickness (height, h) showed that the curves for mechanical fracture (open circle o symbols) and explosion (solid circle • symbols) connect seamlessly at a critical pressure P_{cr} level (Figure 50) [1363]. Tests were done with 10 mm and 17 mm diameter (D) samples of varying heights (h). For the 17-mm samples, the frequency of explosions as a function of D/h ratio went through a maximum. The transition from fracture to explosion takes place at a certain critical stress level of $8500 \text{ kg}_f/\text{cm}^2 = 83.4 \text{ kN}/\text{cm}^2$, indicated by a dashed line in Figure 50.

Figure 50: Pressure at which fracture (1) or explosion (2) of AP crystals occurs, 10 mm diameter samples. (Republished and modified from [1363], with permission of © 1969 Springer Nature BV; permission conveyed through Copyright Clearance Center.)

In drop-weight impact tests of a variety of materials including AP, AP ignited, coinciding with a sharp drop in its pressure-time curve, much like the behavior of RDX [1364]. This can be explained by a dislocation pile-up avalanche model to describe the local-

ized heating associated with such discontinuous load drop behavior and fracturing of the crystal as the load is released.

Following the May 1988 explosion at the PEPCON plant in Henderson, NV, an AP Management Steering Committee was established. In August 1988, a workshop was conducted at the Astronautics Laboratory, Edwards AFB, CA. The 21 experts representing government, industry, and academia attending this workshop developed a three-pronged study program. At the workshop the attendees were divided into three groups to address (1) transportation issues, (2) storage issues, and (3) fundamental properties and reactions. Each group was responsible for defining the major issues, concerns, and questions within their task area, and then for formulating a program plan to address the issues. During the workshop, and in subsequent meetings, the program became defined as the “*Determination of the Responses of AP to Thermal and Mechanical Shock Stimuli*”. In drop weight impact tests with 200 μm AP particles, the 50% threshold drop height was 100 cm, which is roughly two to three times that needed for HMX [650]. The drop height value for a co-crystallized 98:2 mixture of NH_4ClO_4 and KMnO_4 was 75 cm. When initiated by drop weight impact, AP does not propagate explosive response into adjoining material as would a high explosive. Drop weight impact threshold values for AP vary greatly depending on AP particle size and impurities. In the Bundesanstalt für Materialforschung und -prüfung (BAM) drop weight impact tester, the 50% point is at 15 Nm.

The effect of particle size of AP on impact sensitivity and friction sensitivity was systematically studied by using the Chinese standard methods GJB77A-97-601.1 and GJB77A-97-602.1 [1365]. The particle size ranged from 2.7 to 100 μm . The results demonstrated that the friction sensitivities and impact sensitivities of AP increase with the reduction of particle size. Considering that energy is consumed while breaking big particles into small ones, the small friction among the big particles and the sudden extinguishment of thermal decomposition of big particles cause big particles to be less sensitive to impact. The plastic deformation, viscous flow, and the part friction of crystals of small size particles result in an increase of friction sensitivities. The mechanisms and factors affecting mechanical sensitivity were theoretically analyzed from the point of view of physico-chemical changes of the AP ignition mechanism.

SEM, XRD, impact sensitivity, and friction sensitivity testing were done to characterize the micro-structures and mechanical sensitivity of different types of UFAP particles [1366]. The results revealed that the particles were very different in porosity, particle shape and size, crystal regularity degree, and crystal size. The mechanical sensitivity of UFAP samples is affected by so many micro-structural factors that it is difficult to establish a relation between the impact sensitivity and/or friction sensitivity and shape factors. The mechanical sensitivity of UFAP and its dependence on micro-structure can be explained by a hot-spot theory.

The effects of the particle size of AP on its impact sensitivity, friction sensitivity, and the burning rate of the propellants containing AP were investigated [66]. The relationship between particle size and critical initiation electron energy of AP particles,

which could be used to explain the change of sensitivity and burning rate with the particle size of AP, was analyzed.

Looking into what creates hot spots and makes AP crystals ignite during crushing impact, elastic, plastic, and cracking indentation measurements obtained in nano- to micro- to macro-indentation hardness tests of AP and RDX crystals were described on a hardness stress-strain basis and assessed in terms of a dislocation pileup avalanche mechanism for hot-spot generation associated with sudden crack formation [1367, 1368]. The model attempted to interpret particle size influence on the drop-weight height for 50% probability of onset of reaction, extended to include results for ϵ -HNIW crystals. Coatings and additives have been sought that would decrease instead of increase the sensitivity of AP.

10.1.2 Drop Weight Impact Sensitivity of AP Mixtures

The sensitivity of AP toward all stimuli, including drop weight impact, increases as AP becomes accidentally contaminated by or is intentionally mixed with organic combustible substances. Future volumes will contain sections of drop weight impact sensitivity of formulated composite propellants containing AP. Here we list mixtures with ingredients that are not solid propellant binders.

The mechanism of initiation by the impact of mixtures of AP with combustible additives was tested using AP and mixtures of AP with TNT or PMMA [1369]. The value of the critical stress of initiation of AP crystals was 8.5 kbar, while that of mixtures of AP with TNT or PMMA was substantially below that value depending on the AP : additive mixture ratio.

The excitation of an explosion by impact and the propagation of detonation under critical conditions differ in their physical nature but both depend on the interaction of the oxidizer and fuel components. In a study of the impact sensitivity of binary compositions containing AP, potassium perchlorate, or AN with metal powders or organic combustibles like polymers or hydrocarbons, an explanation of the role of chemical interaction between AP dissociation products and the fuel component or the products of its pyrolysis was based on examining processes at the interface between the oxidizer and combustible [1370].

Encapsulation of AP or other oxidizers protects the particles from moisture and aggregation during storage and propellant preparation and improves bonding with binders. Explosive substances like RDX, HMX, and PETN can be desensitized by encapsulation with polymers. However, this is not the case for AP. The opposite effect is observed and the sensitization makes further manipulation of propellant mixtures with coated oxidizers more hazardous. Impact sensitivities of AP coated with eight different polymers including bonding agents and binders were much higher than that of uncoated AP [81]. Coatings by encapsulation caused sensitization, while simple mixing did not lead to the same results. It is believed that the “hot spot” initiated by trapped air bubbles under impact is responsible for the sensitization since at high

polymer concentration the coated AP will recover its insensitivity. Experimental results suggest that particle size and specific heat play roles in sensitization.

A study of the impact sensitivity of two particle sizes of AP (ultra-disperse AP = UDP with particle diameter $d \leq 1 \mu\text{m}$ and nano-disperse AP = NDP with particle diameter $d \leq 0.1 \mu\text{m}$) and their mixtures with various inorganic combustible and inert materials (boron, aluminum, sulfur, carbon, fumed silicon dioxide, etc.) revealed that the mixture of AP with sulfur was the most sensitive combination tested [1371]. The sensitivity was expressed in terms of critical impact pressure σ_s at which a 50% probability of initiation was observed. The σ_s value of UDP was 175 mPa while that of NDP was 220 mPa. The relative position of these two numbers contradicts what has been written in other places about the effect of particle size on sensitivity. The critical pressure for AP/B mixtures was 127 mPa and that of an AP/S mixture was 47 mPa.

10.2 Threshold of Ammonium Perchlorate Detonations

Because AP is transported in bulk containers, the detonability of AP by itself or AP contaminated with other substances has been investigated extensively. We are discussing here only the explosion and detonation properties of AP itself.

The initiation and detonation behavior of 13- μm AP powder and pressed grains was studied at a loading density of 1.00 g/cm^3 [1372]. Steady detonation velocities were determined experimentally at three diameters and extrapolated to $3.75 \pm 0.15 \text{ mm}/\mu\text{s}$ at infinite diameter. Calculations with the Becker–Kistiakowsky–Wilson (BKW) equation of state resulted in $4.25 \text{ mm}/\mu\text{s}$, which is as good an agreement as could be expected for a low-energy chlorine-containing explosive. By introducing 24-kbar flat-topped plane shocks into pellets of various lengths, it was determined that steady full-strength detonation can be reached after about 15 mm of travel. The growth of pressure in the accelerating wave was followed approximately by means of free-surface measurements on thin Plexiglas at the top surfaces of the pellets. These measurements indicated the pressure to be $55 \pm 10 \text{ kbar}$ in the full-strength wave. Reducing the air pressure in the pressings to 5 μm Hg left the rate of pressure build-up to detonation unaffected.

The detonability of finely ground AP is dependent on particle size [1373, 1374], packing density, and charge diameter [1375]. The detonation velocity and critical density ρ_c of AP increased whereas the critical diameter decreased with decreasing particle size. The typical finite diameter D vs ρ_o curve is non-linear and exhibits a maximum in detonation velocity. The failure curve d_c (diameter) vs ρ_c (critical density) reveals a monotonic increase in D_c with ρ_c in the range $\rho_o > \text{ or } = 1.0 \text{ g/cm}^3$ and is opposite in trend to that for TNT. The detonability can be narrowed down more specifically with the card gap test. The gradient of the 50% gap pressure versus loading density curve at higher porosities is similar to that of the TNT curve.

Shock transit times in granular AP at 1.0 g/cm^3 bulk density have yielded a range of shocked states that exhibits a region of apparently positive slope in the pressure/

volume plane between three and ten kilobars and shocked specific volumes greater than the normal value of the crystal between ten and 70 kilobars [1376]. Correspondingly, the range is non-linear in the shock-velocity/particle-velocity plane. Thus, except for extremely weak shocks, AP fails to follow the collapsing aggregate model, a behavior that was ascribed to chemical reactions in initiating shocks. Because the shocked states were calculated from shock and particle velocities measured when the shock first enters the AP aggregate, it was proposed that reaction takes place in the shock front. Hot spots capable of causing such localized reactions have been photographed in large particle-sized aggregates at nominal pressures below 15 kbar.

Decomposition reactions of AP pressurized to 1.5 to 3 GPa were explosive at a heating rate of 10 °C per minute. [157]. Explosion limits were determined by heating compressed pellets of the salt at a slow and constant rate at a fixed pressure. Explosion limit curves (T against P) revealed that explosion temperatures increased with increasing pressure up to 3 GPa. The addition of small amounts of aluminum and copper chromite powders to AP and propellant reduced explosion temperatures from 10° to 60 °C, depending on the pressure.

UFAP handling, storage, and shipping properties were investigated with respect to product coatings, solid propellant formulation processing, and rocket ballistic parameters [43]. Applying hydrophobic coatings introduces combustible organic compounds into an oxidizer, resulting in an increase in the explosive sensitivity of the material. The sensitivity increases with the increasing content of coating material. Dry UFAP will detonate if confined and initiated by a blasting cap or a booster charge, although the detonation velocity may be low or tend to drop off rapidly. UFAP dust generally does not detonate, but one sample (freeze-dried with a relatively high coating content) did detonate in the dust state. AP/halocarbon-F113 suspensions, such as those encountered during the SWECO slurry grinding process, are not detonable as long as the F-113 content is at least 75 mass-%.

UFAP would have to be categorized as Explosive B for shipping purposes. It was attempted to dilute UFAP with coarse beads of an inert material for shipment that could be easily removed at the destination without contaminating the product. It was found that 10% Sorbeads (spherical shaped prills of fused silica gel) would prevent detonation at zero cards in the card gap test. Adding 30% Sorbeads as desensitizer would provide a margin for safety and avoids having to ship UFAP as Explosive B. However, not all grades of UFAP were equally desensitized. One advantage of adding Sorbeads was that they kept the humidity in the shipping container at very low levels and prevent agglomeration. Fumed silica would have the same effect [94].

In order to be on the safe side, a more accurate margin of safety in the deflagration-to-detonation transition of AP was determined [1377]. AP was placed in a sealed tube with reinforced walls and combustion was initiated at one end. The thickness of the tube and the power of the initiation stimulus were varied. AP with additives transits easily from combustion to detonation but pure AP does not do the same. In order to detonate AP, it is necessary to get a small particle size, very strong confinement, and a powerful initiation.

It is difficult to analyze the pressure profiles occurring in stationary detonation propagation in open charges of condensed explosives because of the substantial inhomogeneity. These difficulties can be eliminated by measuring the pressure profile in a wave produced in an intact confining rigid shell, which almost completely excludes lateral escape of energy. An electromagnetic method was used to measure the mass-velocity profile in the detonation of a tamped charge of AP in a strong shell [1378].

AP and AP-based HTPB composite propellant samples were subjected to shock initiation and the pressure was measured with Lagrangian gages [1379]. A pressed AP grain ($\rho = 1.7 \text{ g/cm}^3$) shocked to 4–5 GPa decomposed but did not detonate, while a similar grain shocked to 10 GPa detonated. At a modest shock pressure of 0.08 GPa, AP grains in the HTPB matrix were fractured and broken. Composite propellant containing 67% AP detonated with a velocity of 6.45 mm/s and a C-J pressure of 16 GPa.

It is surprising that 200 μm AP in large bins (with various shipping containers having capacity ranging from 114 kg to 2300 kg [250 to 5000 lbs]), when initiated with a No. 8 cap surrounded by FFF black powder, would just smolder and decompose but never transition to detonation [1341]. AP would slowly burn at one atmosphere pressure where a small mass of AP is heated to its decomposition temperature surrounded by enough insulating layers of AP so that lack of conductive heat loss allowed a slow deflagration to proceed at elevated temperatures. The black powder provided just enough heat to get a mass of AP to begin decomposing and exothermicity of AP decomposition sustained the process going to completion. The complete destruction of the AP in a 5000-lb container took an hour (see [1380] also).

10.3 Detonation Velocity of Ammonium Perchlorate Detonations

The detonation properties of AP (without additives) had been studied experimentally initially only for the (very) porous state. Andersen and Pesante [1381] reported detonation velocities of porous samples of AP and confirmed the dependence of detonation velocity on AP particle size. Their particle sizes were six and 13 μm (mean particle sizes for the various batches). Initiation of the charges to detonation was accomplished by No. 8 blasting caps and various amounts of tetryl booster, depending upon the dimensions of the AP charge. It was observed that steady-state detonation was usually established within about one charge diameter from the booster. Detonation velocities were measured over approximately the second half of the charge length, which is away from the booster and not overdriven. Unfortunately, the scatter in the measurements was significantly large such that “valid” values of D in an infinite geometry for the various densities of AP could not be extrapolated from their data. Nevertheless, they reported a summary equation, relating D and density:

$$D_i = 2688\rho + 1012$$

where D_i is the ideal detonation velocity for large diameter samples in m/s (to within ± 100) and ρ is the density in g/cm^3 . The results for a particle size of $6\mu\text{m}$ shown in Figure 51 were compared to detonation velocities as a function of charge diameter predicted by three different detonation theories: (1) nozzle theory, (2) curved-front theory, and (3) detonation-head theory but the agreement was only vague.

Figure 51: Detonation velocity as a function of charge diameter for different packing densities. (Reprinted and modified from [1381], © 1961, with permission from Elsevier; permission conveyed through RightsLink)

Price, Clairmont, Erkman, and co-workers [1382] built upon the 1961 work of Andersen and Pesante and took great care in preparing high-quality samples for their measurements and in documenting the particle size distributions of the AP batches. They tested a variety of batches (and hence particle sizes) of AP in their extensive studies on AP systems. Al powder was found to decrease the critical diameter when added to AP.

In their summary paper on PAP [1382] it was noted that particle size was not mentioned. Work with finely ground AP led to the infinite diameter relationship

$$D_i = 1.146 + 2.576\rho_o$$

where D_i is the detonation velocity in $\text{mm}/\mu\text{s}$ and ρ_o is the charge density in g/cm^3 over the range $0.55 \leq \rho_o \leq 1.0 \text{ g/cm}^3$. The quadratic mean error found was $0.040 \text{ mm}/\mu\text{s}$. Several computations of D_i as a function of ρ_o were summarized and compared with the experimental data. Estimated limits on the detonation temperatures were proposed [1383]. The lack of particle size information has been

found to be a deficiency in the presentation and analyses of the NOL data. In the 1968 study [1383], detonation velocity measurements were taken for AP mixtures containing 20% of HMX, PETN or 2,2,2-trinitroethyl-4,4,4-trinitrobutyrate (TNETB), indicating an oxidation-reduction reaction but for AP/HMX only. The AP in the other two mixtures contributed to the detonation velocity but the additivity rule does not seem to be applicable to mixtures of AP with organic high explosives.

The addition of fuels such as aluminum or wax will increase the energy output of AP. AP mixed with aluminum powder ("aluminized AP") or wax is a powerful explosive [255]. It could be that some solid propellant formulators would premix the AP and the Al or wax in the dry state before adding the binder but this should not be done without due precautions. Wax coatings may be used to prevent the agglomeration of AP crystals during storage.

AP by itself is not usually used as an explosive but the explosive properties of bulk quantities of AP are a matter of grave concern. In order to calculate the overpressure from accidental AP explosions, the detonation velocity must be known for various charge diameters and methods of initiation.

The detonation velocity of confined AP explosives was determined as a function of the charge diameter and the amount of nitroguanidine additive [1384]. Three particle size ranges of designated coarse (149 to 500 μm), medium (44 to 149 μm), and fine (1 to 44 μm) particles were investigated in a study of the effect of variable AP particle size upon the detonation characteristics of a typical AP composite system sensitized with 5% nitroguanidine [1385]. A decrease in AP particle size, which is already known to increase its propensity to detonate, increased the overall detonation velocity of the AP/NQ system by 5% NQ [1386].

Bulk sound speed measurements, isothermal volume compression/XRD experiments, and shock loading experiments (maximum pressure ~ 20 GPa) were performed for high initial density ($\geq 94\%$ theor. density) AN and AP [118]. The experimental data and full density Hugoniot calculated using that data suggested the presence of low-pressure, shock-induced phase transitions in both AN and AP. The AP phase transition occurs at ~ 4 GPa and exhibits characteristics of a high density to low-density phase transition but the presented data were not conclusive. The AN phase change occurs at a shock pressure of less than 3.5 GPa but the associated volume change is relatively large, indicating the presence of a previously unidentified high-pressure and high-density phase.

Published detonation velocities for AP systems have been reviewed in order to determine values for infinite diameter charges [1387, 1388]. These data have been evaluated in both the detonation velocity-density plane and the detonation velocity-reciprocal diameter plane. The interrelationship between these two planes was examined for both intermolecular and intra-molecular explosive formulations with AP. The importance of particle size in defining detonation velocities D_∞ at infinite diameter for AP-containing formulations is stressed and different interpretations of previously published data were suggested. For AP/wax systems, interesting comparisons have

been made for formulations containing 25 and 200 μm AP. Experimental data for PAP were compared to predictions of detonation velocities based on BKW parameter sets in TIGER.

Plane shock wave experiments were carried out on AP single crystals compressed along [210] and [001] orientations to peak stresses ranging from 1.2 to 6.2 GPa [123]. Quartz gauge and velocity interferometer techniques were used to measure the elastic and plastic shock wave velocities, and to record stress and particle velocity histories in the shocked samples. The measured Hugoniot elastic limit (HEL) was 0.48 ± 0.09 GPa. Above the HEL and up to about 6 GPa, the data revealed a clear two-wave structure, indicating an elastic-plastic response. Time-dependent elastic precursor decay and plastic wave ramping were discernable and orientation-dependent, but only in the low-stress data, although the orientation dependence of the peak state response was small. Data for both orientations were summarized into a single isotropic, elastic-plastic-stress relaxation model. Reasonable agreement was obtained between the numerical simulations using this model and the measured wave profiles. At a shock stress of about 6 GPa and for the time duration and crystal orientations examined, there were no features that could be identified as a sustained chemical reaction or a phase transformation.

10.4 Critical Diameter of Ammonium Perchlorate Detonations

AP of 70 ± 10 μm particle size was used for the following experiments (except the last one where the critical diameter was studied as a function of particle size) [1389]: The critical diameter of AP decreased with a sample temperature from 25 mm at room temperature to 10 mm at 473 K (200 °C), but the mode of confinement and the uncontrolled moisture content caused major variations. It was attempted to extend the experiments to higher temperatures but the AP phase change at 513 K caused the sample volume to swell and the glass tube burst before it could be detonated. Therefore, the samples were only heated to below 493 K. The critical diameter of AP is quite sensitive to the moisture content. It was noted that AP batches that were ground during different seasons of the year had different critical diameters, depending on the ambient relative humidity (winter versus summer) and the amount of moisture the material had picked up while it was ground and sifted. The squares and circles in Figure 52 identify batches processed at different times, named Batch 1 and Batch 2. The critical diameter in a glass tube increased linearly from 20 to 80 mm with a charge density of 1.1 g/cm^3 when the moisture was allowed to increase from 0.01 to 4 mass-%.

AP with 70 μm particle size was compressed to various packing densities and detonated. The critical diameter of AP detonations increased with charge density and so did the detonation velocity. The increase of critical diameter with charge density is somewhat surprising but can be explained in that the void spaces are rapidly compressed by the detonation wave and create hot spots similar to low velocity detona-

tion (LVD) propagation. The circle symbols in Figure 53 indicate data from another source [1381].

The critical diameter of AP detonations decreased substantially and non-linearly with particle size, as shown in Figure 54. The charge density was 1.1 g/cm^3 , which is 56% of solid density. This illustrates the increased hazard in preparing and processing UFAP. The tests were performed with two sample geometries: eighteen to 20 cm

long cylinders with different (constant) diameters and cones with narrowing aspect diameters. The propagation in cones stopped once the critical diameter was reached. The square symbol indicates data from another source [1381]. Figure 3 on page 707 in [1381] shows the critical diameters of AP detonations for different particle sizes, packing density, and charge diameter, which is very useful information.

Figure 54: Critical diameter of AP explosions as a function of particle size. (Reproduced and modified from [1390].)

Other measurements indicate that even with a detonator and two ounces of FFF black powder 200-μm sized propellant grade AP cannot be detonated/exploded despite being detonable in diameters larger than four inches [1341]. The detonation velocity of 56-cm (22-in.) diameter drums of AP has been measured as being about 4 mm/μs. Lower AP detonation shock velocities have been observed at 25.4 cm (10 in.) diameter. Since detonation processes are much quicker than AP phase change, the AP orthorhombic crystal phase is the one typically involved in AP detonations (see [1390, 1374] also).

10.4.1 Modeling of AP Detonations

The detonation behavior of AP was studied to determine the effect of particle size and bulk density on the rate of energy release during detonation [1391]. A slightly divergent detonation model was used to describe the dependence of detonation velocity on charge diameter, and its results were compared to literature data. The chemical kinetic rate law resulting from parameterization of a group of data was then used to describe the heat release rate of the AP system at constant pressure. For low densities, the kinetic form agreed with the concept of hot spot formation and a grain burning reaction. At higher densities, the kinetics were found to exhibit a character more typical for thermal explosions. At any given density, the small particle material revealed a pronounced tendency toward thermal explosion. After solving the constant pressure case, additional calculations covered a pressure-dependent kinetic rate equation.

The compressibility and equation of the state of AP single crystals during shock compression normal to the (210) and (001) crystal planes was determined by velocity interferometer measurements up to 12 GPa [124]. The specific heat c_v , the coefficient of thermal pressure $(\partial P/\partial T)_V$, and the isothermal bulk modulus B_T were determined using Hugoniot and isothermal compression curves, along with available data at atmospheric pressure. It was suggested that any phase transition occurred either with a negligible change in volume or with very slow kinetics (see [227] also).

10.5 Detonation of Ammonium Perchlorate Mixtures

Small amounts of nitroguanidine (NQ) will sensitize AP so it will detonate more easily in a sympathetic detonation mode. Near-ideal detonations of NQ at densities of only 0.18 to 0.015 g/cm³ heavily diluted in AP have been achieved. The addition of NQ evidently induced a sympathetic detonation in the loosely packed AP [1384, 1392]. Amounts of NQ as low as 1% in AP will control the detonation rate of such NQ-AP composites. It appeared that the full energy of the AP is released in the detonation of these composites. It also appeared that charge diameters and confinement did not influence these results except when conditions became such that the AP itself could undergo non-ideal detonation. NQ at even lower concentrations in the vicinity of 0.01 g/cm³ detonated in an explosive composite with about 90% AP at 0.6 cm diameter in steel confinement or at 4 cm diameter in Plexiglass confinement. The detonation velocity of 5% NQ/95% AP was 2.03 km/s and the detonation velocity of 1.25% NQ/98.75% AP was 1.34 km/s. In all these studies the particle size of the AP remained unchanged, nominally 200 μ m Class C MIL SPEC AP. The effects of confinement and charge diameter on AP/NQ detonations were subsequently investigated. A study of the effect of variable AP particle size upon the detonation characteristics of an AP composite system sensitized with 5% NQ used three particle size ranges of designated coarse (149 to 500 μ m), medium (44 to 149 μ m), and fine (0 to 44 μ m) particles. This confirmed a general increase of detonation velocity with a decrease in AP particle size and also identified some anomalous behavior [1386].

10.6 Detonability of Ammonium Perchlorate Mixtures With Other Oxidizers

Occasionally AP is mixed with other oxidizers to achieve optimized performance properties of the mixture. For instance, AN-doped AP is tested as an environmentally more acceptable oxidizer since it releases less hydrogen chloride in its combustion products. However, some of these oxidizer mixtures have also been considered explosives [102, 1393]. Therefore, their safety properties must be known before production processes with such oxidizers are scaled up. Adding AP to explosives may boost their destructive power [1394].

Mixtures of AP with nitromethane are highly detonable and could be used as a two-component explosive. The propagation and extinction of detonation in heterogeneous mixtures of bead AP with mean particle diameters of 9, 35, 90, 200, and 400 μm was measured to study charge diameter effect on detonation velocity and critical diameter. The results were then graphed as a function of the equivalence ratio of the mixture and the size of particles [1395]. The reactive flow sustained by combining unburnt and burnt phases was modeled.

10.7 Explosive Yield of Ammonium Perchlorate

In the Trauzl lead block tests, the cavity volume increase of dry and densely packed AP is $195\text{ cm}^3/10\text{ g}$.

10.8 Friction Sensitivity of Ammonium Perchlorate

High purity 200 μm AP is relatively insensitive to friction with the Julius Peters Model 25 friction tester. Often a 36 kg force (the upper limit for the Julius Peters friction tester) is insufficient to reach AP ignition. AP-based propellants normally have threshold friction ignition values below 12 kg with the Julius Peters machine.

10.9 Bonfire Tests and Cook-Off of Ammonium Perchlorate

An INTERREG, Transport of Dangerous Goods, 1981 Edition, Type 6c bonfire test was conducted consisting of five drums each containing approximately 113.4 kg (250 lb) of AP that was steel-banded together and placed atop a steel crib that was approximately 1 m (3.28 ft) above the ground and surrounded by 0.5 m of lumber drenched with approximately 53 L (14 gallons) of diesel fuel and gasoline mixture (9:1 ratio) [1337]. The entire mass was ignited by two sets of electric matches and 56.7 g (2 oz) of black powder set 180 degrees apart at the base of the stack. The AP was consumed by the fire with no explosions, no overpressure detected, and no rupture, splitting or fragmenting of the drums. Additional information on solid perchlorate oxidizers can be found in [209].

11 Alkali Metal Chlorates and Perchlorates

Alkali metal chlorates have been used heavily in pyrotechnic formulations but their use is decreasing as more environmentally friendly substitutes become available. The problem with any mixture containing chlorates and fuel is their high friction and impact sensitivity. After AP, which was dealt with in the preceding section of this book, the second-most important perchlorate is potassium perchlorate. This is still used in many igniters and other pyrotechnic formulations because it has a much better thermal stability than AP and is less friction sensitive than potassium chlorate in mixtures. Sodium chlorate is mainly used for the onsite generation of OClO used in the pulp and paper industry. It is also used in emergency oxygen generating pyrotechnic formulations. Sodium chlorate is the precursor for sodium perchlorate, which is an intermediate in the production of AP and therefore its properties must be well-known. Lithium chlorate has an unusually low melting point and is very soluble in water. Lithium perchlorate is often used in mixtures with other perchlorates (AP, triaminoguanidinium perchlorate) to improve their properties. Of all the alkali metal perchlorates, LiClO₄ has the highest oxygen content (Table 24).

Table 24: Properties of alkali metal chlorates and perchlorates.

Name	Formula	CAS RN	Molecular mass, g/mol	Total oxygen, mass-%	Available oxygen, mass-%
Lithium chlorate	LiClO ₃	13453-71-9	90.397	53.08	53.08
Sodium chlorate	NaClO ₃	7790-93-4	106.445	45.08	45.08
Potassium chlorate	KClO ₃	3811-04-9	122.554	39.15	39.15
Lithium perchlorate	LiClO ₄	7791-03-9	106.392	60.14	60.14
Sodium perchlorate	NaClO ₄	7601-89-0	122.440	52.25	52.25
Potassium perchlorate	KClO ₄	7778-74-7	138.549	46.18	46.18
For comparison:					
Ammonium perchlorate	NH ₄ ClO ₄	7790-98-9	117.489	54.46	34.03

Although alkali metal and alkaline earth metal perchlorates are not used as rocket propellants, we have included some information on these salts here because they are sometimes used as additives and stabilizers or accelerators for AP and their decomposition mechanisms have been studied and compared to that of AP. The techniques now used for studying the reactivity of metal perchlorates can be later used to study the reactivity of AP and other energetic perchlorate salts, such as those derived from nitrogen bases.

The first edition of this book did not contain a separate chapter on metal perchlorates. They are not used as rocket propellants because the metal oxide thus formed as a combustion product adds to the non-condensables in the exhaust and results in poor

rocket performance. Alkali metal perchlorates are used mostly in pyrotechnic igniter mixtures and airbag gas generants. Properties of metal perchlorates are sufficiently summarized in other publications such as [1–6].

The Pearson 1969 summary in *Oxidation and Combustion Reviews* was preceded by an earlier version published as a government report [7]. The first edition of the Schumacher book was even translated into Russian in 1963. The introduction to Chapter 12 of that book contains sections on the “Environmental Effects of Perchlorates” and “Natural Occurrence of Perchlorates and Toxicity of Ammonium Perchlorate” which apply to alkali metal perchlorates as well.

11.1 Preparation of Alkali Metal Perchlorates

Sodium chlorate is mainly used for the onsite generation of OClO used in the pulp and paper industry. It is produced in a very power-intensive process where the formation of hydrogen bubbles on the cathode surface creates a circulation through the cell. Alkali metal perchlorates are prepared by electrochemical oxidation of the corresponding chlorates.

11.2 Physical Properties of Alkali Metal Perchlorates

The physical properties of alkali metal chlorates and perchlorates are summarized in Table 25. These salts form various hydrates but only the anhydrous salts are listed here.

It is difficult to determine a melting point for potassium perchlorate because of incipient decomposition and the lowering of the melting point due to the presence of decomposition products (KClO_3 and KCl). The melting point appears to be near 853 K (580 °C).

Table 25: Physical properties of alkali metal chlorates and perchlorates.

Name	Formula	Melting point		Density, g/cm ³ at 298 K
		K	°C	
Lithium chlorate	LiClO_3	400.9	127.8	2.596
Sodium chlorate	NaClO_3	521	248	2.489
Potassium chlorate	KClO_3	629–641	356–368	2.32
Lithium perchlorate	LiClO_4	509–530	236–247	2.429
Sodium perchlorate	NaClO_4	745	472	2.536
Potassium perchlorate	KClO_4	883 (dec.)	610 (dec.)	2.53

11.2.1 Solubility of Alkali Metal Perchlorates

The solubility of alkali metal perchlorates is of interest in the production and purification of perchlorates via recrystallization. It is also of interest for the recovery of perchlorates from propellants and pyrotechnic formulations that are demilitarized by leaching out the oxidizers. Environmental pollution by perchlorates has been identified as a major, long-lasting problem, and solubilities of perchlorates in water and other solvents must be known. The solubilities of alkali metal perchlorates have been summarized in Tables 26 and 27 [144].

Table 26: Solubility of alkali metal perchlorates in water.

Metal perchlorate	Solubility, g solute per 100 g of solution, at 298 K
Lithium perchlorate	37.5
Sodium perchlorate	67.8
Potassium perchlorate	2.0
For comparison:	
Ammonium perchlorate	20.0
Hydroxylammonium perchlorate	90.7

Data source: [1396]

Table 27: Solubility of alkali metal perchlorates in organic solvents.

Salt	Solubility, g salt per 100 g solvent, at 298 K		
	LiClO ₄	NaClO ₄	KClO ₄
Solvent

11.2.2 Thermodynamic Properties of Alkali Metal Perchlorates

The thermodynamic properties of alkali metal chlorates and perchlorates are summarized in Table 28. These salts form various hydrates but only the anhydrous salts are listed here.

Table 28: Thermodynamic properties of solid alkali metal chlorates and perchlorates.

Name	Formula	Heat capacity near 298 K		Enthalpy of formation, at 298 K		References
		J mol ⁻¹ K ⁻¹	cal g ⁻¹ °C ⁻¹	kJ/mol	kcal/mol	
Lithium chlorate	LiClO ₃	—	—	–369.0	–88.2	[1397]
Sodium chlorate	NaClO ₃	—	—	–365.8	–87.422	[1397]
		—	—	–360.3	–86.12	[1398]
Potassium chlorate	KClO ₃	100.2	23.96	–397.7	–95.06	[1397]
		—	—	–391.2	–93.66	[1398]
Lithium perchlorate	LiClO ₄	105	25.1	–380.74	–90.88	[202]
		—	—	–380.27 ± 1.21	–90.89 ± 0.29	[209]
Sodium perchlorate	NaClO ₄	111.22	26.6	–382.75	–91.5	[202]
		—	—	–382.75 ± 0.93	–91.48 ± 0.22	[209, 1398]
Potassium perchlorate	KClO ₄	110.97	26.52	–430.12	–102.8	[202, 1398]
		—	—	–431.9 ± 0.6	–103.22 ± 0.15	[1399]

The standard heat of formation of anhydrous lithium perchlorate is –383.6 kJ/mol (–91.70 kcal/mol) [1400]. The heat of solution of anhydrous lithium perchlorate and lithium perchlorate trihydrate in water (450 H₂O) at 298 K is –26.2 ± 0.1 kJ/mol (–6.25 ± 0.03 kcal/mol) and –33.1 ± 0.1 kJ/mol (–7.91 ± 0.03 kcal/mol), respectively.

11.3 Chemical Properties of Alkali Metal Perchlorates

11.3.1 Reactions of Alkali Metal Perchlorates

Anhydrous lithium perchlorate forms a stable adduct with dinitrogen tetroxide. This compound is formed if an excess of N₂O₄ is condensed onto LiClO₄ in a pressure vessel, allowed to stand at room temperature for a day or so, and the excess N₂O₄ evaporated and then pumped off at room temperature [1401]. The residue appears unchanged but it has gained weight according to LiClO₄•N₂O₄. Similar adducts can be formed with Mg(ClO₄)₂ or Ca(ClO₄)₂.

Lithium perchlorate and sodium perchlorate form hydrazinates with hydrazine [1402]. Independent of the concentrations of the starting materials, the complexes obtained were LiClO₄•2N₂H₄ and NaClO₄•N₂H₄. On grinding, the solid

complexes detonated but gentle heating in air or in vacuo in an open volume leads to the removal of the co-ordinated N_2H_4 without a detonation. IR spectra of $\text{LiClO}_4 \cdot 2\text{N}_2\text{H}_4$ revealed the presence of an ionic ClO_4^- (1100 cm^{-1}). A shift of N_2H_4 bands from the position of a free N_2H_4 molecule band indicated co-ordination to the Li^+ ion.

The dihydrazinate-perchlorate of lithium melts without decomposition but the monohydrazinate-perchlorate of sodium decomposes before melting. The alkali metal perchlorate hydrazinates are thermally not very stable and may auto-ignite upon heating [1403]. The compounds do not have a sharp melting point but gradually lose solvated hydrazine during heating before melting.

The combustion of the dihydrazinate-perchlorate of lithium and the monohydrazinate-perchlorate of sodium has been studied at 0.1–7 MPa. The oxidation of the combustible part of the complexes was incomplete. There was a clear relation between the rate of combustion and the surface temperature of the charge. The rate of combustion was determined by the oxidation of the hydrazine in the surface layer (molten) of the condensed phase [1404].

11.3.2 Thermal Decomposition of Alkali Metal Perchlorates

Good summaries on the thermal decomposition of alkali metal and alkaline earth metal chlorates and perchlorates (as well as bromates, perbromates, iodates, and periodates) are provided in [1398, 1405]. An earlier summary is now mostly of historical interest [1406]. These publications contain hundreds of literature references relating to this subject.

One of the most practical methods for the study of the decomposition of perchlorates and other energetic materials is by DTA [1407]. It has been noted that some of the energy released during exothermic decomposition of perchlorates is derived from crystallization of the higher melting chlorides as decomposition products.

When examining the rates of oxygen evolution during the decomposition of Na, K, Rb, and Cs perchlorates between 623 and 773 K, which were almost the same, it was suggested that the rate-controlling factor was a property of the ClO_4^- ion rather than the crystal lattice of the solid. This is possible if the neighboring ClO_4^- ions participate in a bimolecular interaction [1408]. The decomposition rates were determined by direct measurement of the O_2 evolution rate using a time-of-flight mass spectrometer. All four salts had nearly the same rate of decomposition below 683 K (410°C). Above 683 K (410°C) the rate of NaClO_4 was abnormally high.

A comparative study of the polymorphic transformations in ammonium and the alkali metal perchlorates using DTA developed correlations between the observed trends in the transformation temperatures and available crystallographic and thermodynamic data between these two groups of perchlorates [111]. Prior mechanical and thermal treatment resulted in a broadening of the hysteresis loops in the case of potassium perchlorate [743].

11.3.2.1 Thermal Decomposition of Lithium Perchlorate

LiClO_4 and NaClO_4 melt before they decompose. Because the activation energy of the decomposition reaction is about 270 kJ/mol, it was concluded that the rate-limiting step is the breaking of a Cl—O bond [1409]. The difference in behavior between sodium perchlorate and the other alkali metal perchlorates has been explained on the basis of the stability of the respective chlorates, formed during the LTD. This is substantiated by experiments that found that the addition of sodium chlorate to sodium perchlorate brings about a sensitization while potassium perchlorate admixed with potassium chlorate results in desensitization at high temperatures. Lithium perchlorate is stable in the melt at temperatures up to 663 K (390 °C). The degree of decomposition versus time curve of LiClO_4 exhibits an induction period and its shape is sigmoid, indicating an autocatalytic decomposition reaction.

The thermal decomposition of pure lithium perchlorate and in admixtures with lithium chloride was studied across the temperature range of 665–688 K (392–415 °C) by using constant temperature thermogravimetry [1410]. It was shown that above 520 K (247 °C) any mixture of lithium perchlorate with its decomposition product, lithium chloride, always contains the perchlorate in solution. Over the temperature range covered, the kinetics followed an autocatalytic rate law ($E_{\text{act.}} = 218 \pm 17 \text{ kJ/mol} = 52.2 \pm 4.1 \text{ kcal/mol}$) up to about 40% decomposition and then conform to first-order kinetics ($E_{\text{act.}} = 259 \pm 17 \text{ kJ/mol} = 62.0 \pm 4.1 \text{ kcal/mol}$). The point of transition between the two rate laws occurred when the decomposing melt was saturated with lithium chloride (see [1411]).

The isothermal decomposition of liquid lithium perchlorate in the presence of AgClO_4 has been studied between the temperature range of 523 and 673 K (250 and 400 °C) [1412]. The final products are primarily LiCl (precipitated as AgCl) and O_2 . Some ClO_2 and ClO_3^- is produced as an intermediate. The addition of lithium chlorate enhanced the decomposition. The relationship between this liquid melt decomposition and that of the solid alkali perchlorates [1408] was then discussed.

11.3.2.2 Thermal Decomposition of Sodium Perchlorate

Many alkali metal and earth alkaline metal perchlorates crystallize from aqueous solutions. Varying amounts of water is incorporated into the crystal lattice during crystallization. The water of hydration must be removed before the perchlorates can be used in rocket propellants and pyrotechnic formulations. In some cases, the chlorate or perchlorate may start to decompose before all water is removed. The dehydration of sodium perchlorate monohydrate proceeds in two stages corresponding to the removal of 0.2 H_2O and 0.8 H_2O per mol at 333 K (60 °C) and 423 K (150 °C), respectively [1413]. The thermal decomposition at 763 K (490 °C) was preceded by a phase transformation at 582 K (309 °C) (orthorhombic $\rightarrow$ cubic) and melting at 745 K (472 °C). Between 763 and 793 K (490 °C and 520 °C), the fractional decomposition (α) versus time (t) curves for molten NaClO_4 in vacuum were sigmoidal, thus indicating an autocatalytic process. The α , t isothermal data were best fitted by a first order autocatalytic

equation over the temperature range 763–793 K (490–520 °C). The activation energies for the two simultaneously occurring processes were 289.3 ± 5.4 and 208.9 ± 3.8 kJ/mol, respectively. The final solid product of the decomposition was sodium chloride in all cases.

Sodium chlorate is thermally stable to well above its melting point. Decomposition starts near 673 K (400 °C). No Cl_2 or ClO_2 is formed during its decomposition. In contrast to the chlorate, the sodium perchlorate starts to decompose below its melting point. Therefore, it is difficult to determine the melting point of this chemical. In the decomposition of sodium perchlorate, sodium chlorate that is formed as an intermediate product decomposes just as fast as it is formed. Sodium perchlorate monohydrate loses water in a two-step process below 473 K and there is a phase transition between 569 and 588 K.

It is known that crystals that are undergoing decomposition often make crackling noises but very rarely have the noises been recorded and related to other evidence of decomposition that is in progress. Simultaneous measurements of acoustic emission (AE) by thermosonimetry (TS) and DTA during the thermal decomposition of KClO_4 and $\text{NaClO}_4 \cdot \text{H}_2\text{O}$ revealed that the AE technique successfully followed rapid decomposition and phase transition of these salts [1414]. In the case of KClO_4 , two extra AE signals were detected at 373–473 K (100–200 °C) and 474–573 K (200–300 °C), at which point no simultaneous thermal effect was observed on the DTA curve.

Melting and decomposition of NaClO_4 started at 723 K and continued up to 843 K. For NaClO_4 , TS curves corresponding to melting/decomposition and solidification of molten NaCl were found to consist of six peaks [1415]. During the decomposition of KClO_4 , three TS peaks appeared. The origin of these TS peaks is discussed on the basis of thermomicroscopic observations during which melting of the particles, evolution of bubbles of different sizes, the formation of solid products of varied morphologies, vigorous vibration of these solids, and precipitation of NaCl or KCl were observed.

11.3.2.3 Thermal Decomposition of Potassium Perchlorate

Potassium perchlorate, KClO_4 , underwent an endothermic phase transition from orthorhombic to cubic between 553 and 603 K. Melting and incipient exothermic decomposition starts at 858–903 K [1399]. If one plots the degree of conversion versus time, the curves for KClO_4 have a sigmoid shape and the pattern of kinetic behavior cannot be linked to a particular nucleation or autocatalyzed growth process. The acceleratory phase begins when the reactant forms a molten eutectic with its decomposition products (anions that contain less than four oxygens). The decomposition is a combination of concurrent and reverse reactions

The decomposition of KClO_4 is self-accelerating by a factor of 50 once decomposition starts.

When studying the thermal decomposition of (1) potassium perchlorate in powdered form, (2) potassium perchlorate in pelletized form, (3) potassium perchlorate recrystallized from liquid NH_3 , and (4) potassium perchlorate preheated for 24 hours at 648 K (375 °C) using DTA, it was discovered that the pre-treatment of potassium perchlorate leads to a desensitization of both endothermic and exothermic processes [1416]. The pre-treatment tends to convert the symmetric exotherm into an asymmetric exotherm due to the merging of the two exotherms. An analysis of the factors causing asymmetry in the exotherm has contributed toward understanding the mechanism of thermal decomposition of potassium perchlorate. The DTA of KClO_4 showed two endotherms, one at 573 K (300 °C) corresponding to the phase transition from orthorhombic to cubic and another around 873 K (600 °C) corresponding to melting of the eutectic mixture. The two endotherms were followed by an exothermic reaction. Other investigators found that KClO_4 has two endotherms and two exotherms. The first exotherm appeared after the melting endotherm at 879 K (606 °C). Its exothermicity decreased as it reached 909 K (636 °C). At this point, a sharp rise in exothermicity occurred, with a peak at 914 K (641 °C) followed by the rapid decay of the exotherm.

DTA was used to understand the influence of particle size on the decomposition of KClO_4 [1417]. DSC curves of KClO_4 , with different particle sizes, revealed an endothermic peak from a phase transition close to 581 K (308 °C) and a melting point at 881 K (608 °C). DTA curves produced similar results. The percentage of mass loss in the TGA curves of decomposition for the reaction of $\text{KClO}_4 \rightarrow \text{KCl} + 2\text{O}_2$ was close to the theoretical value (46.18%). The initial decomposition temperature of KClO_4 with smaller particle sizes was shifted to lower temperatures, and the decomposition activation energies of KClO_4 ranged from 231 to 269 kJ/mol.

11.3.2.4 Effects of Catalysts on Perchlorate Thermal Decomposition

The effects of catalysts, typically metal oxides known to be active as burning rate catalysts, on the thermal decomposition of AP has already been described in detail. Similar studies were performed on the thermal decomposition of alkali metal perchlorates in the presence of catalysts, and the insights gained from those tests can help in the interpretation of decomposition mechanisms of AP, which is of significantly greater practical interest than the alkali metal perchlorates. The effect of burning rate catalysts, mostly metal oxides and mixed metal oxides on the burning rate and rate of thermal decomposition of perchlorates by themselves and in propellant and gas generant compositions has been extensively investigated (See Section 4.6.8.1). In an attempt to determine if the catalysts aid in the decomposition of the ammonium ion or the perchlorate ion, many of the experiments have been repeated with alkali metal perchlorates instead of AP. Catalysts investigated included iron(III) oxide, manganese(IV) oxide, and others.

The catalytic decomposition of sodium and potassium chlorates and perchlorates was examined by TGA at low temperatures where there is practically no dissociation in the absence of a catalyst [1418–1420]. These experiments used salt crystals with a diameter of 0.14–0.20 mm mixed with 1% MnO_2 and heated. The degree of decomposition of the specimen (300 mg) was recorded by using TGA. Surface diffusion apparently plays an important role in reaction kinetics.

As observed via DTA and gas evolution measurements, KClO_4 and NaClO_4 , on heating at $4.5^\circ/\text{min}$, underwent an endothermic phase change at 579 and 577 K (306 and 304°C), melting at 848 and 741 K (575 and 468°C), respectively. They then decomposed with the liberation of two mols of oxygen gas at 893 and 834 K (620 and 561°C) [1421]. LiClO_4 did not undergo a phase change but melted at 514 K (241°C) and decomposed at 762 K (489°C). In the presence of a catalyst made of a 2:1 mixture of MnO_2 and NiO , decomposition occurred at 793, 701, and 645 K (520, 428, and 372°C) for KClO_4 , NaClO_4 , and LiClO_4 , respectively. Following a critical evaluation of literature data, the heat of formation of KClO_4 was selected as -426 kJ/mol (-101.9 kcal/mol).

The effects of $\alpha\text{-Fe}_2\text{O}_3$ and $\alpha\text{-Al}_2\text{O}_3$ additives on the thermal decomposition of perchlorates were investigated by means of DTA, TGA, and XRD [1422]. It was found that the oxide additives catalytically promoted the decomposition of perchlorates [NaClO_4 , KClO_4 , and $\text{Mg}(\text{ClO}_4)_2$] and resulted in a lowering of the initial decomposition temperature. When comparing the catalytic effect of twelve metal oxides, the transition metal oxides such as Cr_2O_3 , $\alpha\text{-Fe}_2\text{O}_3$, and CuO markedly accelerated the decomposition of potassium perchlorate. These oxides resulted in a solid-phase decomposition before fusion of KClO_4 . The initial decomposition temperature of KClO_4 with oxides was about $100\text{--}200^\circ\text{C}$ lower than that without catalyst. Inert oxides such as $\alpha\text{-Al}_2\text{O}_3$ and MgO resulted in a slight lowering of the temperature of the fusion and promoted the molten-phase decomposition of KClO_4 , but their effects were not as remarkable as those of the transition metal oxides. The catalytic mechanism of transition metal oxides may involve electron transfer and oxygen abstraction.

The thermal decomposition of potassium perchlorate in the presence of various metal oxides was investigated by programmed TGA and by isothermal weight loss techniques [1423]. The effect of metal oxide concentration on the temperature of initial deflection, T_i , of TGA curves of metal oxide/potassium perchlorate mixtures was determined. The Arrhenius parameters were tabulated to demonstrate the effect of metal oxide concentration on the activation energy and rate of decomposition of potassium perchlorate.

The catalytic effect of $\alpha\text{-Fe}_2\text{O}_3$ on the thermal decomposition of KClO_4 was studied using TGA and DTA methods [1424]. DTA and TGA curves showed that the addition of $\alpha\text{-Fe}_2\text{O}_3$ led to an acceleration effect on the solid-state decomposition of KClO_4 . The acceleration effect increased with a decrease in the preparation temperature and an increase in the amount of $\alpha\text{-Fe}_2\text{O}_3$ added. The decomposition rate constant, k , was estimated from TGA curves by assuming a first-order rate law. An Arrhenius plot of k demonstrated a straight line that had a sharp bend at the temperature T_B , which was

characteristic of the respective $\alpha\text{-Fe}_2\text{O}_3$ sample. It was suggested that the solid-state decomposition proceeded below T_B and the liquid-state decomposition above T_B . The activation energy of the solid-state decomposition, E_a , of pure KClO_4 was 328 kJ/mol (78.4 kcal/mol) and those of $\text{KClO}_4 + \alpha\text{-Fe}_2\text{O}_3$ mixtures were 224, 252, and 254 kJ/mol (53.6, 60.2, and 60.8 kcal/mol) for the oxide prepared at 773, 923, and 1273 K (500, 750, and 1000 °C), respectively. The activation energy of the liquid-state decomposition, E_a , for pure KClO_4 was 633 kJ/mol (151.4 kcal/mol) and those of $\text{KClO}_4 + \alpha\text{-Fe}_2\text{O}_3$ mixtures were in the range 618–642 kJ/mol (147.8–153.4 kcal/mol).

In a similar series of tests, the effect of copper/manganese oxides (MnO_2/CuO in different atomic ratios $[\text{Cu}/(\text{Cu} + \text{Mn}) = x$, where $x = 0\text{--}1]$ on the rate of non-isothermal decomposition of KClO_4 was measured. The results were interpreted assuming an electron transfer mechanism [1425]. The enhancement effect of trace Cu(II) added to the host oxide MnO_2 was attributed to an increase in the exchange capacity of manganese cations between the different oxidation states. The retarding effect associated with Cu(II) -rich samples was attributed to the trapping of the electrons required to initiate the decomposition reaction by the lattice defect holes created. On the basis of the applicability of a non-isothermal kinetic equation, it was demonstrated that two main stages are involved in the decomposition process.

The catalytic effect of chromites on the non-isothermal decomposition of KClO_4 was studied using TGA and DSC [1426]. Reactions of KClO_4 -alkaline earth chromites mixtures indicated the formation of $\text{K}_2\text{Cr}_2\text{O}_7$, through a solid-solid interaction, before accelerating the decomposition stage of KClO_4 . Such an accelerating effect became more pronounced in the case of admixing KClO_4 with some transition metal chromites. The kinetic parameters and models describing the catalyzed thermal decomposition process of KClO_4 were evaluated by using a computer program that facilitated analysis using five different methods. It was found that the adopted kinetic model for pure KClO_4 and that mixed with catalysts is a one-dimensional movement of phase boundary. On the other hand, a random nucleation mechanism was achieved in the presence of other catalysts.

12 Alkaline Earth Metal Chlorates and Perchlorates

Because alkaline earth metals are bivalent, they can carry two chlorate or perchlorate ions instead of only one as in the alkali metal salts. That gives a potentially higher percentage of oxygen in the molecule. Unfortunately, most alkaline earth perchlorates are extremely hygroscopic; so hygroscopic that magnesium perchlorate is being used as a desiccant (Anhydron[®]), which is easier to use and clean up than phosphorus pentoxide. Properties of alkaline earth metal chlorates and perchlorates are summarized in Table 29. These salts form various hydrates with water but only the anhydrous salts are listed here. The solubilities of alkaline earth metal perchlorates have been summarized in [145]. These salts also form stable complexes where ammonia or hydrazine

Table 29: Properties of alkaline earth metal chlorates and perchlorates.

Name	Formula	CAS RN	Molecular mass, g/mol	Total oxygen, mass-%
Magnesium chlorate	Mg(ClO ₃) ₂	10326-21-3	191.21	50.20
Calcium chlorate	Ca(ClO ₃) ₂	10137-74-3	206.98	46.38
Strontium chlorate	Sr(ClO ₃) ₂	7791-10-8	254.52	37.72
Magnesium perchlorate	Mg(ClO ₄) ₂	10034-81-8	223.206	57.34

For comparison:				
Ammonium perchlorate	NH ₄ ClO ₄	7790-98-9	117.489	54.46

is absorbed as the ligands. We have omitted the lowest members of this family, poisonous beryllium chlorate and beryllium perchlorate, because it is unlikely that anyone would want to use them as rocket propellants due to their toxicity. Magnesium perchlorate crystallizes with six mols of water in the hydration sphere.

12.1 Physical Properties of Alkaline Earth Metal Chlorates and Perchlorates

The physical properties of alkaline earth metal chlorates and perchlorates are summarized in Table 30. These salts form various hydrates but only the anhydrous salts are listed here.

In view of the discovery of perchlorates on Mars and their possible contributions to saturated aqueous solutions saline brine capable of surviving in underground aquifers at the low atmospheric pressure of Mars, the physical properties of alkaline earth perchlorates and their solutions have gained new significance.

Table 30: Physical properties of alkaline earth metal chlorates and perchlorates.

Name	Formula	Melting point		Density, g/cm ³ at 298 K	Enthalpy of formation kJ/mol
		K	°C		
Calcium chlorate	Ca(ClO ₃) ₂	613	340	2.71	—
Strontium chlorate	Sr(ClO ₃) ₂	393 (dec.)	120 (dec.)	3.15	—
Magnesium perchlorate	Mg(ClO ₄) ₂	524	251	2.21	−568.90 or −588.3
Calcium perchlorate	Ca(ClO ₄) ₂	543	270	2.651	−736.76
Strontium perchlorate	Sr(ClO ₄) ₂	—	—	3.02	—
Barium perchlorate	Ba(ClO ₄) ₂	778	505	3.2	−796.26 ± 1.35

Various metal (K^+ , Na^+ , Ca^{2+} , Mg^{2+} , Fe^{2+} , Fe^{3+} , and Al^{3+}) perchlorate salts were studied to provide spectral and thermal data for remotely detecting and characterizing their possible presence on Mars [1427]. Spectral and thermal analyses in combination with structural analyses were needed to understand how different cations and different hydration levels affect the perchlorate mineral system in the soil. Near-IR spectral features for perchlorates are dominated by H_2O bands that occur at 0.978–1.01, 1.17–1.19, 1.42–1.48, 1.93–1.99, and 2.40–2.45 μm . Mid-IR spectral features are observed for vibrations of the tetrahedral ClO_4^- at $1105\text{--}1130\text{ cm}^{-1}$ ($\sim 8.6\text{--}9\text{ }\mu m$), $760\text{--}825\text{ cm}^{-1}$ ($\sim 12\text{--}13\text{ }\mu m$), 630 cm^{-1} ($\sim 15.9\text{ }\mu m$), $460\text{--}495\text{ cm}^{-1}$ ($\sim 20\text{--}22\text{ }\mu m$), and $130\text{--}215\text{ cm}^{-1}$ ($\sim 50\text{--}75\text{ }\mu m$). The spectral bands in both regions are sensitive to the type of cation present because the polarizing power is related to the band center for many of the spectral features. DSC data revealed variable patterns of water loss and thermal decomposition temperatures for perchlorates with different cations, consistent with changes in spectral features measured under varying hydration conditions. Results of the DSC analyses indicated that the bond energies of H_2O in perchlorates are different for each cation and hydration state.

Perchlorates found in the Martian regolith offer a new opportunity for ISRU [1428]. Mars offers an abundant source of perchlorates with confirmed measured concentrations upwards of 1% detected at two landing sites. Methods for extracting perchlorate compounds and separating them into more useable constituents are under consideration. Potential uses are *in-situ* breathing oxygen production and solid oxygen candles for astronauts. An additional and promising use would be the direct mixing of the perchlorate compounds as the solid oxidizer in a solid rocket motor configuration using a suitable binder and fuel combinations. The first settlers will have to take a small chemical factory with them to make use of this resource.

Alkaline earth metal perchlorates form energetic complexes with carbohydrazide. The crystal structures, density of states, energy gap, thermodynamic properties, impact sensitivities, and the morphology of alkaline-earth metal carbohydrazide perchlorates $[Me(CHZ)_3](ClO_4)_2$, $Me = Be, Mg, Ca, Sr, Ba$, were investigated using the DFT and crystal morphology theory [1429].

12.1.1 Thermodynamic Properties of Alkaline Earth Metal Chlorates and Perchlorates

The enthalpies of solution of N_2H_4 complexes of Mg , Ca , Sr , and Ba perchlorates in diluted HCl were related to the enthalpies of solution of the metal perchlorates in water [1430]. The standard enthalpies of formation were calculated for the complex salts $M(ClO_4)_2 \cdot 2N_2H_4$ ($M = Mg, Ca, Sr, \text{ and } Ba$) and $M'(ClO_4)_2 \cdot N_2H_4$ ($M' = Ba, Sr, \text{ and } Ca$) and similar ammonia complexes.

12.2 Properties of Specific Alkaline Earth Metal Chlorates and Perchlorates

12.2.1 Magnesium Perchlorate

Magnesium perchlorate is very hygroscopic and decomposes at above 523 K (250 °C). It is sold under the trade name Anhydron[®] or Dehydrite[®]. It is used as a desiccant to dry gas samples or to dry solid samples in a desiccator, however, it is no longer advised for use as a general desiccant due to potential hazards posed by perchlorates in contact with combustibles. It can be regenerated by applying heat at 493 K (220 °C) under vacuum. Magnesium perchlorate is stable up to 320 °C when carefully dried. In the presence of moisture, it may decompose at temperatures below 320 °C. Traces of moisture lower its melting point substantially. The heat of formation of magnesium perchlorate is -568.90 kJ/mol.

Anhydrous magnesium perchlorate forms a stable adduct with dinitrogen tetroxide. This compound is formed if an excess of N₂O₄ is condensed onto Mg(ClO₄)₂ in a pressure vessel, allowed to stand at room temperature for a day or so, and the excess N₂O₄ is evaporated then pumped off at room temperature [1401]. The residue will appear unchanged but it will have gained weight according to Mg(ClO₄)₂•N₂O₄. The density was 2.199 g/cm³ (compared to 2.21 g/cm³ for Mg(ClO₄)₂). It decomposed when heated above 344 K (70 °C) and evolved brown fumes. Similar adducts can be formed with LiClO₄ or Ca(ClO₄)₂.

12.2.2 Calcium Perchlorate

Calcium perchlorate is very hygroscopic. The most common way of keeping it in the laboratory is in the form of its calcium perchlorate tetrahydrate, Ca(ClO₄)₂•4H₂O.

12.2.3 Strontium Perchlorate

The heat capacity of Sr(ClO₄)₂ at 10–340 K was measured by using vacuum adiabatic calorimetry and the standard thermodynamic functions were derived [1431]. Strontium perchlorate is an ingredient in pyrotechnic formulations. Injection of strontium perchlorate solutions into solid propellant motor nozzles was used for thrust vector control.

12.2.4 Barium Perchlorate

Barium perchlorate is used as the oxidizer in some igniter pyrotechnic mixtures. Barium perchlorate decomposes at 778 K (505 °C). The heat capacity of Ba(ClO₄)₂ at 10–350 K was measured via vacuum adiabatic calorimetry and standard thermodynamic functions were derived [1432]. Barium perchlorate is an ingredient in pyrotechnic formulations.

12.3 Other Metal Perchlorates

Another metal perchlorate that is frequently used for metathetical reactions in the synthesis of energetic organic amine perchlorates is silver perchlorate.

Perchlorates of polyvalent metals like titanium or chromium can form perchlorates with more than two perchlorate ions in the molecule and a correspondingly very high available oxygen content. Titanium tetraperchlorate and chromyl perchlorate can be prepared using chlorine perchlorate and the respective metal chlorides [1433, 1434].

These anhydrous metal perchlorates were found to contain bidentate perchlorato ligands. The thermal stability of $\text{Ti}(\text{ClO}_4)_4$ was examined in closed bomb tests. After one hour at 388 K (115°), the decomposition was incomplete, as evidenced by the recovery of less than the theoretical amount of oxygen in the form of O_2 and Cl_2O_7 . After four hours at 388 K (115°C), approximately half the oxygen content of the $\text{Ti}(\text{ClO}_4)_4$ was converted to O_2 and half to Cl_2O_7 .

Chromyl perchlorate is a dark red liquid with less than 1 mm vapor pressure at room temperature. Its high reactivity and low stability precluded successful transfers for property measurements. $\text{CrO}_2(\text{ClO}_4)_2$ decomposed on heating according to the equation:

AP or lithium perchlorate can form double salts with boron perchlorate or aluminum perchlorate, which might make useful solid propellant oxidizers, but they are not very stable and no applications have been reported. Very little has been published about these double salts. Properties of some of these double salts are listed in Table 31.

Ammonium or lithium perchlorate forms complex perchlorates with $\text{Al}(\text{ClO}_4)_3$ or $\text{Zn}(\text{ClO}_4)_2$ resulting in the formation of $\text{NH}_4\text{Al}(\text{ClO}_4)_4$ and $\text{LiZn}(\text{ClO}_4)_3$ [1436].

13 Nitronium (Nityl) and Nitrosonium (Nitrosyl) Compounds

It has been attempted to use the tetrafluoroborates and perchlorates of nitrosyl (NO^+ , also called nitrosonium) and nityl (NO_2^+ , also called nitronium) cations as rocket propellant oxidizers. This concept is especially attractive because not only the anion (as in traditional solid propellant oxidizers) but also the cation contributes useful oxygen. These compounds have the highest available oxygen content of any solid oxidizer known to chemists.

In organizing the vast amount of information on rocket propellant oxidizers, a decision had to be made of whether nitrosonium and nitronium oxidizer salts should be discussed under nitrogen oxides where the cation is derived from or under various chapters for the anions like perchlorate and tetrafluoroborate. A similar decision had

Table 31: Properties of perchlorate double salts.

Data source: [1435]

to be made for the oxonium salts. It was decided to give the cations priority over the anions for the simple reason that we are used to listing the cation part of salts first and the anion part last. Perchlorates of nitrogen bases (amines, heterocyclic nitrogen bases) are discussed along the same lines in *Encyclopedia of Liquid Fuels*, under fuels, although some of them are potential oxidizers. At least the free amines from which they are derived are liquid fuels.

In the early days of nitronium (nitryl) chemistry, it was assumed that the reaction of nitric acid with perchloric acid would produce “nitracidium” perchlorates, the cation being a singly (or even doubly) protonated nitric acid. This was caused by problems with removing adhering nitric acid from the nitronium perchlorate product. This delayed the recognition of NO_2^+ as an entity of its own.

Nitrosonium and nitronium compounds are difficult to prepare and most are thermally unstable. Since none of them have found practical applications so far, we discuss them here mostly for their academic interest. They are very moisture sensitive and will hydrolyze spontaneously.

Whereas traditional inorganic oxidizers, such as potassium nitrate or potassium perchlorate, carry the alkali metal cation only as ballast and actually an oxygen sink, the nitrosonium and nitronium cations contribute useful oxygen to the overall oxygen balance of the compounds. Some nitrosonium and nitronium compounds, e.g., the fluorides and chlorides, are liquids and have more covalent bond character. Some of them have already been discussed in *Encyclopedia of Oxidizers*, chapter “Nitrogen Fluorides”. The nitrosonium and nitronium compounds discussed here have more saline character and are solids at room temperature. That is one reason why some chemists suggest that the words nitryl and nitronium should designate two different forms of NO_2 : a covalent bond bound form and an ionized salt form. The same has been argued for nitrosyl and nitrosonium.

Nitronium and nitrosonium salts can be prepared via the interaction of nitryl and nitrosyl chloride with anhydrous HF and Lewis acid fluorides [1437].

13.1 Nitronium (Nitryl) Salts

The most stable nitronium compound appears to be the nitronium tetrafluoroborate $\text{NO}_2^+\text{BF}_4^-$. This salt has been widely used to achieve nitrations, nitrosations, and diazotizations in organic chemistry. It can also be used as an intermediate in preparing nitronium perchlorate via metathetical reactions. It has also been proposed as an oxidizer in rocket propellants, however, it would be less energetic than the perchlorates.

13.1.1 Nitronium Perchlorate

The most attractive compound as a rocket propellant in this category of oxidizers with unusual cations is nitronium perchlorate, NO_2ClO_4 , also known as nitryl perchlorate

or nitroxyl perchlorate, CAS RN [17495-81-7], which has a useful oxygen content of 66 mass-%. A very good summary of nitronium perchlorate properties is provided by Pearson [2] on pages seven through to 15.

13.1.1.1 Preparation of Nitronium Perchlorate

Nitronium perchlorate was first discovered in the reaction products of concentrated perchloric acid and white fuming nitric acid. This reaction does not produce pure NO_2ClO_4 but a mixture of several compounds, including perchloric acid monohydrate and a double perchlorate $[\text{H}_3\text{O}^+][\text{NO}_2^+][\text{ClO}_4^-]_2$. The formula for the double perchlorate has also been written in the form $[\text{H}_3\text{NO}_3^{++}][\text{ClO}_4^-]_2$. For a long time, nitronium perchlorate was made by a liquid-phase reaction of dinitrogen tetroxide with perchloric acid in nitromethane as a solvent. Products from this procedure lacked thermal stability.

A better procedure is the reaction of dichlorine heptoxide with nitric acid. This forms a white solid, which is a mixture of anhydrides of perchloric acid and nitric acid, from which nitronium perchlorate must be sublimed under vacuum to separate it from the less volatile perchloric acid [1438]:

The unstable Cl_2O_7 is prepared via a dropwise addition of HClO_4 to P_2O_5 at 195 K (-78°C). This is a very slow reaction because the HClO_4 freezes as soon as it contacts the cold wall. The Cl_2O_7 generation takes place as the reaction mixture is left to thaw slowly. The Cl_2O_7 is not isolated as such (it is very explosive) but is distilled at a reduced pressure (1–2 mm Hg, 313 K = 40°C) directly into stirred white fuming nitric acid or red fuming nitric acid with a dehydrating agent such as P_2O_5 , while cooling the reacting mixture in a dry ice bath. The H_3PO_4 formed must then be removed via solvent extraction. Possible side reactions in this system are:

An excess of nitric acid reacts with the perchloric acid to form nitrosonium perchlorate, which may contaminate the desired product:

If the formation of nitrosonium perchlorate is undesirable, one should work with at least a 1:1 molar ratio of Cl_2O_7 and HNO_3 . Maintaining a slight excess of Cl_2O_7 , one should work in the presence of a dehydrating agent like P_2O_5 . Mixtures of nitronium perchlorate and nitrosonium perchlorate can be separated by fractional crystallization in nitromethane as the solvent.

Nitronium perchlorate with better than 99% purity can be obtained via the reaction of dinitrogen pentoxide with anhydrous perchloric acid [1439]:

Nitrosonium perchlorate, if present as a contaminant, rarely exceeds 0.2%.

Research was initiated to produce uniform spherical particles of nitronium perchlorate in sizes up to at least 20 mesh having near perfect density. Originally, the plan was to spray-dry the nitronium perchlorate; however, it was later decided that a more promising initial approach would be to apply pan-coating techniques to the problem [1440].

Nitronium perchlorate can be obtained in higher purity and a more stable form via the reaction of dinitrogen pentoxide and chlorine trioxide in the vapor phase. Another method used nitrogen dioxide and OClO in the presence of ozone under pressure (689 kPa = 100 psig) [1441].

Studies of reactions and adduct formation in the ternary system $\text{Cl}_2\text{O}_7\text{-N}_2\text{O}_5\text{-H}_2\text{O}$ identified three compounds with increasing stability (in that order) [1442, 1443]:

Another method used a gaseous mixture of nitrogen dioxide, chlorine, and ozone and irradiated it with UV or gamma radiation in the reaction zone [1444].

Nitronium perchlorate can be made from ozonized air reacting with OClO or nitrogen dioxide in ozonized air reacting with OClO [1445]. Instead of making OClO from sodium chlorite and sulfuric acid, OClO can be prepared in a pre-reactor from dry chlorine gas and ozone. The NO_2ClO_4 thus obtained is a white solid with a density of 2.2 g/cm^3 . It decomposed at 393 K (120 °C) and had a drop-weight impact sensitivity of 120 kg-in.

Optimum yields (90%) can be obtained with ClO_2 and NO_2 gases premixed before entering the reactor, an operating temperature between 328 and 348 K (55 and 75 °C), and a $\text{ClO}_2:\text{NO}_2$ molar ratio of 1.0 to 1.3 [1446]. An improved method of synthesizing nitronium perchlorate works by oxidizing chlorine nitrate with ozone [1447].

13.1.1.2 Physical Properties of Nitronium Perchlorate

Nitronium perchlorate forms monoclinic crystals with a density of 2.25 g/cm^3 at 298 K and vapor pressure at 298 K is 10^{-4} mm Hg . Other sources reported the density as 2.220 g/cm^3 at 298 K and the standard heat of formation as $+8.7 \text{ kJ/mol}$.

Raman spectra of solid NO_2ClO_4 and several other nitronium salts confirmed the ionic structure of the crystals [1448].

IR spectra of NO_2ClO_4 were measured in the range 2–15 μ with NaCl optics in the range of 15–20 μ . CsBr optics and significant absorption bands were at 2360, 1100, 937,

625, and 570 cm^{-1} [1449]. There was no significant absorption beyond 20μ . The band at 2360 cm^{-1} is the ν_3 fundamental vibration of NO_2^+ .

The Raman spectrum of crystalline nitronium perchlorate exhibits ten well-resolved lines plus an additional weak line appearing as a shoulder [1436, 1450]. The IR spectrum consists of moderately intense absorptions at 940 and 2300 cm^{-1} and a strong broad absorption around 1100 cm^{-1} , which (on closer examination) may be resolved into three peaks. This information supports the structure of nitronium perchlorate crystals already obtained by XRD. An interpretation of these data points at the bending mode of the nitronium ion with cation-anion interaction in crystalline nitronium salts.

13.1.1.3 Thermodynamic Properties of Nitronium Perchlorate

The enthalpy of solution and hydrolysis of nitronium perchlorate was determined in an isothermal calorimeter. From that number, the enthalpy of formation of crystalline nitronium perchlorate was calculated as $+33.5 \pm 1.7\text{ kJ/mol}$ ($+8.0 \pm 0.4\text{ kcal/mol}$) [1451].

In another experiment, the heat of formation of nitronium perchlorate was determined via hydrolysis with aqueous KOH in a calorimeter and was measured as $+37.19 \pm 1.0\text{ kJ/mol}$ ($+8.89 \pm 0.25\text{ kcal/mol}$) [1452].

13.1.1.4 Molecular Structure of Nitronium Perchlorate

Early XRD examination of nitronium perchlorate confirmed that the crystal structure contains the ions NO_2^+ and ClO_4^- [1453]. The structure of nitronium perchlorate, NO_2ClO_4 , has been investigated via a three-dimensional analysis [1454]. There are four formula units in a monoclinic unit cell with the structure parameters $a = 9.16\text{ \AA}$, $b = 7.08\text{ \AA}$, $c = 7.30\text{ \AA}$, $\beta = 112.1^\circ$ and space group $C/2c$. An apparent anomaly in the electron density of one of the oxygen atoms was explained by the anisotropy of the thermal motion. After anisotropic refinement ($R = 0-13$), the bond lengths were calculated as $\text{Cl}-\text{O} = 1.464 \pm 0.007\text{ \AA}$ and $\text{N}-\text{O} = 1.10 \pm 0.01\text{ \AA}$ in ions, which are slightly distorted from the tetrahedral and linear forms, respectively. The $\text{N}-\text{O}$ distance was reported as $1.15 \pm 0.01\text{ \AA}$ in nitronium nitrate and this value was confirmed by a new refinement of the published data. Chlorine 3-D orbitals are involved in a strong π bonding system in the perchlorate ion. The nitronium perchlorate crystals are monoclinic, space group $C2/c$, with $a = 9.25\text{ \AA}$, $b = 6.99\text{ \AA}$, $c = 7.34\text{ \AA}$, $\beta = 113.5^\circ$ [1455]. It has been suggested that NO_2ClO_4 , even at ambient temperatures, has some covalent character, as substantiated by XRD, vibration spectra, and its ability to sublime.

13.1.1.5 Chemical Properties of Nitronium Perchlorate

Nitronium perchlorate is very moisture-sensitive and thermally unstable. It decomposes without melting. It begins to decompose at 323 K (50°C) and the rate of decomposition is significant above 333 K (60°C) (see next chapter). Nitronium perchlorate reacts violently with many organic compounds, causing spontaneous ignition. This limits the type of binders that can be used in combination with nitronium perchlorate

to make solid propellants. Nitronium perchlorate can be dissolved in nitromethane as a solvent and then used as a nitrating agent in organic preparative chemistry.

Dissolving nitronium perchlorate in liquid dinitrogen tetroxide converts it quantitatively to nitrosonium perchlorate. Nitronium perchlorate has been suspected as an intermediate in the thermal decomposition of AP.

Nitronium perchlorate forms complex perchlorates with $\text{Al}(\text{ClO}_4)_3$ or $\text{Zn}(\text{ClO}_4)_2$ resulting in the formation of $\text{NO}_2\text{Al}(\text{ClO}_4)_4$ and $\text{NO}_2\text{Zn}(\text{ClO}_4)_3$ [1456]. It also forms an adduct with pyridine [1457]. The composition of the white salt is $(\text{C}_5\text{H}_5\text{N})_{1.5}\text{NO}_2\text{ClO}_4$. In contrast to uncomplexed NO_2ClO_4 , the pyridine complex salt is not hygroscopic; it dissolves only slowly in water and hydrolyzes very slowly. The salt is thermally stable but only below 353 K (80 °C) and the drop weight impact sensitivity with the Olin tester is 20 kg-cm with a 2 kg weight.

13.1.1.6 Thermal Stability and Decomposition of Nitronium Perchlorate

Nitronium perchlorate is thermally unstable. It begins to decompose at 323 K (50 °C) and the rate of decomposition is significant above 333 K (60 °C). Nitrosonium perchlorate is somewhat more stable than nitronium perchlorate [1458] but when nitrosonium perchlorate is decomposed, some nitronium perchlorate can be found in the residue. The following reactions are likely steps in the NO_2ClO_4 decomposition reactions:

The thermal decomposition of solid nitronium perchlorate has been studied by measuring the rate of pressure rise in a constant volume flask over a temperature range from 343 to 385 K (70 to 112 °C) [1459]. The fractional rates of decomposition are independent of sample size. The rate constants are

$$k_{\text{initiation}} = 10^{12.6 \pm 0.5} e^{-28.5 \pm 0.8 \frac{\text{kcal}}{\text{mol}} / RT} \text{ s}^{-1}$$

and

$$k_{\text{growth}} = 10^{12.5 \pm 0.6} e^{-27.5 \pm 0.9 \frac{\text{kcal}}{\text{mol}} / RT} \text{ s}^{-1}.$$

The reaction is delayed by an induction time

$$t_{\text{induction}} = 10^{-15.0 \pm 0.9} e^{+30.7 \pm 1.5 \frac{\text{kcal}}{\text{mol}} / RT}.$$

Based on thermal decomposition studies at 373–433 K (100–160 °C) using isothermal constant volume techniques and by using mass spectrometry, the activation energy was found to be $15 \pm 1 \text{ kcal/mol}$ [1460]. This is in good agreement with the energy of photolysis derived from the absorption edge of the absorption spectrum.

Analyzing the isothermal decomposition products of a sample at 338 K (65 °C) under vacuum with a mass spectrometer shows that the initial product of decomposition is mostly oxygen [1461, 1462]. The decomposition proceeds in four stages:

- (1) sublimate deposits on cooler parts of the system,
- (2) an induction period of 24–40 hours during which no gas evolution takes place,
- (3) an initially slow but rapidly accelerating production of oxygen which reached a maximum after being exposed to heat for 100 hours, accompanied by the appearance of a yellow condensate in a cold trap, and
- (4) gradually decreasing rate of oxygen production.

There is no residue. Products observed during the latter stages of the decomposition (NO_2 , Cl_2 , ClO_2) are attributed to the decomposition of nitronium perchlorate. If NO_2 forms at any stage of the NO_2ClO_4 decomposition, it would quickly convert it to NOClO_4 . If the NO_2 is immediately removed by keeping the sample under a vacuum, its autocatalytic effect is avoided because the NO_2 is pumped off as soon as it is formed. The isothermal NOClO_4 decomposition results of Marshall and Lewis [1461, 1462] have been interpreted such that nitronium perchlorate decomposes into nitronium perchlorate and oxygen with subsequent decomposition of the nitronium perchlorate.

The thermal decomposition of nitronium perchlorate has been studied in the range from 70 to 112 °C [1463]. A kinetic study of the overall decomposition revealed that

- (1) the decomposition is an autocatalytic process;
- (2) there is an induction period with a slow, nearly constant gas evolution (corresponding to 0.5% decomposition);
- (3) except for minor changes in the induction period, there is no variation with sample sizes;
- (4) the decomposition gives approximately 3 mols of gas per mol of nitronium perchlorate decomposed;
- (5) the maximum rate occurred when the fraction decomposed, α was approximately 0.2;
- (6) during the acceleration period, α was proportional to t^4 ; and
- (7) after the maximum, $d\alpha/dt$ showed a linear decrease with increasing α .

After the induction period, the process consists of a first-order initiation of nuclei followed by the three-dimensional growth of these nuclei. A suggested modification of the theory included a mobile equilibrium of the active sites and the interpretation that the particle size referred to a sub-crystalline unit. The decomposition can be represented by the following equations:

Moisture caused the decomposition of nitronium perchlorate and the evolution of gas. Essentially, there was more gas in a moister storage condition.

The kinetics and mechanism of the thermal decomposition of nitronium perchlorate were examined in the temperature range of 353 to 443 K (80–170 °C) using isothermal constant-volume methods and simultaneous DTA-TGA [1464]. To suppress sublimation of the salt, the study was conducted under dry He at a pressure of 100 mm Hg. DTA and TGA data revealed the presence of three distinct stepwise weight loss processes and a crystal phase change at about 429 K (156 °C). These mass loss processes were interpreted as (1) the conversion of nitronium into nitrosonium perchlorate, (2) a reversal of step (1), and (3) the destruction of nitronium perchlorate into only gaseous products. Kinetic analysis of the data indicated that stages (1) and (2) obeyed a Prout-Tompkins relation, indicating a branching-nuclei mechanism. Data from step (3) fit the contracting-cube expression $k_t = 1 - (1 - \alpha)^{1/3}$ and suggested the possibility of decomposition by ion-pair evaporation from the surface.

The thermal stability of nitronium perchlorate is usually measured by observing the pressure of an evacuated sample held in a glass bulb with an attached manometer. The stability can be changed in either direction by co-crystallization with salts containing aliovalent anions or cations (see below).

The kinetics of gas evolution from nitronium perchlorate irradiated with UV light from a high-pressure Hg arc lamp has been investigated as a function of intensity, temperature, and the duration of UV irradiation [1465]. Different gaseous products of decomposition were identified via mass spectrometry, the predominant species being O₂ and NO. The data indicated that two primary mechanisms for photolysis were operating simultaneously. The first mechanism started out rapidly, built up to a speedy rate of photolytic decomposition, and then subsided with time. The second slower mechanism then took over and was responsible for the longtime photolytic behavior. A UV absorption spectrum of a single crystal of nitronium perchlorate was also measured. The results agreed with the threshold energies for photodecomposition.

A thermobarogravimetric technique using a METTLER thermal analyzer was used to study the fundamental parameters of sublimation processes for solids that sublime and decompose simultaneously [1466]. The technique was applied to nitronium perchlorate and the resulting data has been kinetically analyzed by using the contracting volume model for sublimation. These data were consistent with models of the irreversible thermal decomposition of nitronium perchlorate. The activation energy of sublimation of nitronium perchlorate below 373 K (100 °C) was 78.2 kJ/mol (18.7 kcal/mol) and 60.2 kJ/mol (14.4 kcal/mol) between 383 and 423 K (110 and 150 °C).

The effects of adding impurities to nitronium perchlorate were investigated using simultaneous DTA and TGA and via isothermal constant-volume decomposition with pressure measurement [1467]. The impurities were chosen to increase the number of cation vacancies and the number of anion vacancies and to produce steric hindrance effects. The thermal stability of nitronium perchlorate can be improved by the addition

of an excess of cation vacancies and ions. This produces a cation-anion interaction in the lattice and vice-versa. The thermal stability is decreased by an excess of anion vacancies.

The thermal decomposition of NOClO_4 (powder, or fragments of pressed pellets) and of NO_2ClO_4 (granules) was studied gasometrically and by XRD [1468, 1469]. During the decomposition of NOClO_4 , NO_2ClO_4 was formed as an intermediate. The following mechanism was suggested for the decomposition of NOClO_4 :

Some of the NO_2 dimerized to N_2O_4 , which can react in its ionic form. The last reaction would then be with N_2O_5 as an intermediate:

Nitronium perchlorate NO_2ClO_4 was assumed to become partly reduced to NOClO_4 during heating but others could not confirm the intermediacy of NOClO_4 . The maximum rate of oxygen evolution was at a degree of conversion of $\alpha = 0.3 - 0.4$. Independent of the composition of the initial sample, the reaction mixture will always contain both perchlorates.

The rate of decomposition of nitronium perchlorate at constant temperatures of 300 to 333 K (80 to 140 °F) was determined by measuring the weight loss of modified Kjeldahl flasks from which the accumulating decomposition products were periodically removed [1470]. The decomposition rates are based on data accumulated during tests lasting from 550 hours to 28 months. The results indicated a much slower decomposition rate than extrapolations from higher temperature data would indicate. Results also revealed that the incorporation of a fluorocarbon binder had little effect on the decomposition rate.

Stabilizers and Inhibitors for Nitronium Perchlorate

Investigations of the reactions of NO_2ClO_4 with various ligand molecules were made in an effort to increase the size of the NO_2^+ cation, and thereby improve the stability of NO_2ClO_4 [1471, 1472].

Attempts were made to improve the chemical stability of nitronium perchlorate by forming nitronium ion complexes [1473]. This approach was unsuccessful because of the general failure of NO_2^+ to form stable complexes. Pyridine was the only molecule found to produce a solid complex with NO_2ClO_4 . The pyridine complex ($\text{NO}_2(\text{py})_x\text{ClO}_4$) slowly decomposed at room temperature to a brown tar, which contained pyridinium perchlorate.

Nitronium perchlorate stabilization studies included an examination of the early stages of thermal decomposition, analysis of a contaminate, optimization of

a treatment procedure, studies on the mechanism of stabilization, and a semi-empirical additive screening study [1463]. It was attempted to prepare stabilized nitronium perchlorate by using additives, new isolating techniques, and by using new synthesis techniques starting with ultra-pure raw materials. The primary objective was the preparation of nitronium perchlorate, which had no gas evolution at 333 K (60 °C) over 100 hours. In addition to this primary goal, it was realized that the ultimate use of nitronium perchlorate is dependent on its long-term stability. Since the decomposition of nitronium perchlorate has been characterized as an autocatalytic process, the start of the accelerated decomposition phase is critical to its long-term stability. Therefore, a secondary objective of studies was to identify factors that inhibit or retard the onset of the accelerated decomposition. Decomposition studies showed that changes in the decomposition process occurred during the early stages of decomposition. Gas evolution during the induction period was unrelated to the length of the induction period.

Studies on nitronium perchlorate stabilization showed that BF_3 had a significant stabilizing effect. This initial finding was based on contacting “as received” nitronium perchlorate with BF_3 . Stabilization by boron trifluoride is only of limited utility. For some samples containing BF_3 , the treatment was equivalent to drying and resulted in lower gas evolution. For other samples, contacting with BF_3 had little if any effect. Stability tests run in the presence of BF_3 indicated lower gas evolution but BF_3 was still consumed.

Other studies indicated that the stabilizer in water-treated nitronium perchlorate is hydronitracidium perchlorate, $\text{H}_3\text{NO}_3(\text{ClO}_4)_2$, which actually is a mixed crystal system of hydronium perchlorate and nitronium perchlorate. This implies that stabilization is affected by the modification of the crystal structure of the surface layers of nitronium perchlorate. Originally, it was thought that ultra-dry nitronium perchlorate was the key to stability. Another stabilization method is the coating of nitronium perchlorate with another oxidizer. Although nitronium tetrafluoroborate no longer looked attractive as a crystal modifier, the use of ammonium tetrafluoroborate or AP was still considered.

Infrared and electron paramagnetic resonance spectroscopy was employed to measure the reactivity of nitronium perchlorate with various organic materials, including a solid propellant binder [1474]. The results indicated that compatibility between raw nitronium perchlorate and the binder system is less than satisfactory. Testing of the reactivity of simple hydrocarbons with nitronium perchlorate showed that *n*-hexane, *n*-pentane, and isooctane reacted slowly with nitronium perchlorate at ambient temperatures, and HNO_3 , NO_2Cl , N_2O , and CO_2 were the major reaction products. Methane did not appear to react. OClO is inherently present at low concentrations in dry commercial nitronium perchlorate. Concentrations are slightly higher in undried nitronium perchlorate. The formation of ClO_2 can be used as a qualitative measure of the reactivity of organic materials with nitronium perchlorate.

Nitronium perchlorate is very hygroscopic and susceptible to hydrolysis in the presence of water. Thus, is it very surprising that anyone would want to stabilize nitronium perchlorate via controlled exposure to a trace amount of water followed by evacuation to remove the reaction products after aging for several days to allow the reaction to penetrate the crystals [1475]. As an indication of improved stability, the time delay for the onset of accelerated decomposition at 333 K (60 °C) was delayed from 100 hours to 1000 hours.

It has been found that the thermal stability of nitronium perchlorate can be improved by adding an excess of cation vacancies and ions. This produces a cation-anion interaction in the lattice and vice-versa. It has been shown that thermal stability is decreased by an excess of anions [1476, 1477]. Only small mol fractions of additives, typically 10^{-2} , are required to achieve this effect due to crystal lattice defects. The addition of sulfate anions accelerated the decomposition of NO_2ClO_4 , whereas the addition of $\text{Ca}(\text{ClO}_4)_2$ or $\text{Sr}(\text{ClO}_4)_2$ stabilized the NO_2ClO_4 . Double salts like $(\text{NO}_2)_3\text{Al}(\text{ClO}_4)_6$ or $\text{NO}_2\text{Zn}(\text{ClO}_4)_3$ were substantially more stable than NO_2ClO_4 itself. Another way to stabilize nitronium perchlorate is to expose it to boron trifluoride gas [1478]. The sample will absorb 0.01 to 1% BF_3 to achieve this effect.

Low-melting eutectic mixtures with other perchlorates and nitrates can be melt-cast into an inert liquid to form spherical oxidizer particles. These can be coated and encapsulated with polymers (polyvinyl chloride, polyvinylidene chloride) [1444] or metalized with aluminum to protect them from moisture and to process them into solid propellants with a binder [1479, 1480]. The preferred eutectic point mixture contains 60% nitronium perchlorate and 40% lithium perchlorate and melts at 365 K (~92°C), which is below the decomposition temperature of nitronium perchlorate (Figure 55).

Another method to encapsulate nitronium perchlorate is to expose the particles slowly to an atmosphere of ammonia diluted in an inert gas [1481]. This converts a thin layer on the surface to AP, which is less hygroscopic than nitronium perchlorate.

13.1.2 Nitronium Tetrafluoroborate

Nitronium tetrafluoroborate NO_2BF_4 is easy to prepare via the reaction of nitryl fluoride with boron trifluoride. Nitryl fluoride is first prepared via the reaction of dinitrogen pentoxide with hydrogen fluoride and then saturated with BF_3 . Nitronium tetrafluoroborate is well crystallized and is an important intermediate in the preparation of other nitronium compounds or for the preparation of nitramines from their parent secondary aliphatic amines [1482].

Hypergolic propellant combinations obtained by bringing NO_2BF_4 and Lewis adducts of BF_3 with N_2O_3 , N_2O_4 or N_2O_5 in contact with organic amines, polyamines, alkyl hydrazines, or glycols have been proposed [1483]. NO_2BF_4 and Lewis adducts of BF_3 with N_2O_3 , N_2O_4 , or N_2O_5 are solids. It is therefore difficult to understand how these solid oxidizers could be combined with liquid fuels unless it is done in a reverse hybrid rocket engine. However, the ignition delays quoted in the patent

Figure 55: Melting point diagram of binary NO_2ClO_4 - LiClO_4 mixtures. (Reproduced and modified from [1480].)

(15 to 30 seconds, **not** milliseconds!) are much too long for practical applications. 1,1-Dimethylhydrazine hydrochloride was an unfortunate choice of fuel. Since it is already protonated, it would be expected to react more slowly than the free hydrazine.

13.2 Lewis Adducts of BF_3 with N_2O_3 , N_2O_4 or N_2O_5

Because the Lewis adducts of BF_3 with N_2O_3 , N_2O_4 , or N_2O_5 are closely related with NO_2BF_4 , we are discussing these compounds in a subdivision of the chapter on NO_2BF_4 . Except for the one obscure example listed in the previous section, they have not received widespread consideration as rocket propellants. The Lewis adducts of BF_3 with N_2O_3 , N_2O_4 , or N_2O_5 can be prepared by the direct addition of the Lewis base (nitrogen oxides with free electron pairs) to the Lewis acid (BF_3 with an electron gap). The 1:1 addition complex of boron trifluoride with dinitrogen tetroxide is an excellent nitrating agent. Boron trifluoride also forms a similar 1:1 complex with dinitrogen trioxide. The complex is a white, stable solid, insoluble in all solvents with which it does not react, including alkanes, nitroalkanes, and polychlorinated alkanes. It sublimates at room temperatures and does not melt in a sealed tube below 573 K (300 °C). These properties suggest that the complex is ionic in character. The

$\text{BF}_3 \cdot \text{N}_2\text{O}_3$ complex reacts rapidly with substances with which BF_3 and N_2O_3 by themselves would react as well, including water, alcohols, ethers, ketones, carboxylic acids, and amines.

13.3 Nitrosonium (Nitrosyl) Salts

13.3.1 Nitrosonium Perchlorate

Nitrosonium perchlorate, nitrosyl perchlorate, $[\text{NO}^+][\text{ClO}_4^-]$, CAS RN [15605-28-4] is of little interest as a rocket propellant since it is thermally less stable than nitronium perchlorate and contains less oxygen. It ignites hypergolically with many amines and ammonia gas.

13.3.1.1 Preparation of Nitrosonium Perchlorate

Nitrosonium (nitrosyl) perchlorate can be prepared via the reaction of cold 70% HClO_4 with excess dinitrogen tetroxide in 99% HNO_3 at 268–263 K (–5 to –10 °C) [1484].

The reaction of dichlorine heptoxide with nitric acid which forms a white solid, which is a mixture of the anhydrides of perchloric acid and nitric acid. Nitronium perchlorate can be sublimed from this mixture under vacuum to separate it from the less volatile perchloric acid [1438]:

An excess of nitric acid reacts with the perchloric acid to form nitrosonium perchlorate:

The yield of NOCIO_4 in the reaction of N_2O_4 and HClO_4 is limited by the hydrolysis of NOCIO_4 by the water formed in the reaction. Water must constantly be removed via a reaction with P_2O_5 to obtain a good yield of NOCIO_4 .

A simple method avoids the use of perchloric acid by starting with sodium perchlorate monohydrate and concentrated sulfuric acid, achieving nitrosyl perchlorate in 65% yield based on the $\text{NaClO}_4 \cdot \text{H}_2\text{O}$ used [1485].

13.3.1.2 Physical Properties of Nitrosonium Perchlorate

Nitrosonium perchlorate forms rhombic crystals with a density of 2.169 g/cm³ at 298 K. When heated, nitrosonium perchlorate decomposes without melting.

The standard enthalpy of formation of solid nitrosonium perchlorate was once estimated as –154 kJ/mol (–36.8 kcal/mol). Calorimetric measurement of the heat of reaction

resulted in a heat of formation of solid nitrosyl perchlorate as -165.7 ± 1.2 kJ/mol (-39.6 ± 0.3 kcal/mol) [1486].

13.3.1.3 Chemical Properties of Nitrosonium Perchlorate

In the presence of moisture, nitrosonium perchlorate hydrolyzes to nitrous acid and perchloric acid:

Only a few organic polymers are suitable for protective coatings of nitrosonium perchlorate to protect it against moisture. Polyvinyl chloride is compatible with nitrosonium perchlorate and can be used for this purpose. Nitrosonium perchlorate will ignite hypergolically with many amines and ammonia.

13.3.1.4 Thermal Stability of Nitrosonium Perchlorate

Nitrosonium perchlorate is stable at room temperature. It has no melting point but begins to decompose below 373 K to form nitrogen oxides and chlorine [1487]. The decomposition is complete at 413 K. The initial decomposition reaction may be

but these intermediate products are not stable either. The overall decomposition reaction is more like

In another isothermal thermal stability test at 365 K and 3–5 mm Hg vacuum, the weight losses after three, six, nine, and 12 hours were 27, 61, 94, and 100%, respectively [1488]. At 373 K, the losses after three, six, and nine hours were 65, 80, and 99%, respectively. In similar tests at 372 K and 1 mm Hg, nitronium perchlorate was found in the solid residue [1489]. The mechanism leading to nitronium perchlorate is assumed to go by

The presence of NO_2ClO_4 in the decomposition products was verified by XRD [1490]. DTA thermograms revealed two peaks, the first at 373–398 K (100–125 °C), which was assumed to be nitrosonium perchlorate decomposition. The second was at 438–453 K (165–180 °C), which was assumed to be nitronium perchlorate decomposition [1491].

The reaction of nitrosonium perchlorate with metal halogenides is a convenient method for the preparation of metal perchlorates by a solid-solid using a metathetical reaction where the only solid reaction product is the desired perchlorate salt [1492].

14 Other Non-Metal Perchlorates

Covalent inorganic perchlorates were prepared from chlorine perchlorate. The compound $\text{I}(\text{ClO}_4)_3$ was partially characterized and $\text{N}(\text{ClO}_4)_3$ was deduced as a short-lived primary reaction product. The one-valent iodine(I) perchlorate could not be prepared but a complex perchlorate of iodine(III), $\text{CsI}(\text{ClO}_4)_4$, was indeed synthesized [1493].

Iodine tris(perchlorate) was prepared via the low-temperature reaction of iodine with an excess ClOClO_3 [1494]. Its composition was established by quantitative synthesis:

with the material balance for all components being 99%. The compound is a white solid, stable at 228 K (-45°C). During its synthesis, no explosions were encountered. However, when exposed to a laser beam, explosive decomposition occurred even at low temperatures. It decomposed upon warming to ambient temperature. Extreme caution is advised as chlorine perchlorate is shock sensitive and samples of both $\text{I}(\text{OClO}_3)_3$ and $\text{Cs}^+\text{I}(\text{OClO}_3)_4^-$ have exploded even at low temperature while recording their laser Raman spectra. Proper safety precautions must be taken when working with these compounds. The salt $\text{Cs}^+\text{I}(\text{OClO}_3)_4^-$ was prepared according to

It is a pale yellow solid and is stable at room temperature.

Chlorine perchlorate (ClOClO_3) can be prepared using the reaction of cesium perchlorate or nitronium perchlorate with chlorine fluorosulfate or chlorine monofluoride [1495]. Bromine perchlorate (BrOClO_3) can be prepared using a similar reaction of cesium perchlorate or nitronium perchlorate with bromine fluorosulfate or via the reaction of chlorine perchlorate with elemental bromine.

Boron perchlorate $\text{B}(\text{ClO}_4)_3$ has been prepared from boron trichloride and anhydrous perchloric acid at 195 K (-78°C) [1496, 1497]. It is very unstable and can decompose explosively. It may form double salts with nitronium perchlorate or AP.

The two hydrazinium perchlorates will be discussed in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salts”.

Hydroxylammonium perchlorate will be discussed in *Encyclopedia of Oxidizers*, chapter “Hydroxylammonium Salts”.

The properties of alkylammonium perchlorates are discussed at the end of each parent amine chapter in *Encyclopedia of Liquid Fuels*, chapter “Aliphatic Amines”.

Red Fuming Nitric Acid

Nitric Acids

Although chemically speaking there is only one nitric acid with the formula HNO_3 , we have subdivided this chapter on nitric acids into three subchapters in *Encyclopedia of Oxidizers*, dealing with four technical grades of nitric acids of different chemical composition: **white fuming nitric acid** (WFNA), **red fuming nitric acid** (RFNA), and mixed acid (MA). There are two variants of RFNA, **inhibited red fuming nitric acid** (IRFNA) and **high-density acid** (HDA).

1 Red Fuming Nitric Acid

Many of the physical properties of RFNA are like those of WFNA. Thus, if no better data are available, one can use the WFNA data in first approximation or prorate properties from mixtures of WFNA and dinitrogen tetroxide, N_2O_4 (NTO) assuming additive behavior.

1.1 Production of RFNA

RFNA can be made by simply mixing liquid N_2O_4 and HNO_3 in the appropriate ratios in a closed reactor with agitation to achieve complete mixing. The heat of mixing is exothermic. Corrosion inhibitors can be added in a subsequent operation.

1.2 Physical Properties of RFNA

Summaries of physical and chemical properties of RFNA can be found in [1] and [2]. Summaries of the physical and chemical properties of RFNA and HDA are found in [3]. The physical properties of RFNA as a function of the N_2O_4 content can be quickly looked up with the help of a nomograph [4, 5].

1.2.1 Freezing Point and Phase Diagrams of RFNA

The most effective and practically important freezing-point-depressing additive to nitric acid is dinitrogen tetroxide to form RFNA. The addition of N_2O_4 to HNO_3 not only lowers the freezing point but also improves rocket performance. In most cases, RFNA contains not only HNO_3 and N_2O_4 but may also contain an inevitable (and even desirable) trace of water.

The freezing point diagram of the binary system $\text{HNO}_3/\text{N}_2\text{O}_4$ is presented in Figure 1. A very old National Advisory Committee for Aeronautics (NACA) report contains a freezing point diagram that covers the entire composition range in the $\text{HNO}_3/\text{N}_2\text{O}_4$ binary system [6].

Figure 1: Freezing point of binary nitric acid-dinitrogen tetroxide system. (Reproduced and modified from [7].)

Note: This acid contained 0.4% water.

The interrelated effects of water, from 0 to 10 mass-%, and dinitrogen tetroxide, from 0 to 25 mass-%, in fuming nitric acid were investigated with respect to the freezing points of the acid mixture and the ignition delays with several hypergolic fuels [7]. An equilibrium freezing-point surface for the acids in the composition range studied is presented. A minimum freezing point of 206.2 K (−88.5 °F) occurs in a region of approximately 5% water and 17% dinitrogen tetroxide. A binary eutectic line extends from this region to nearly anhydrous acid containing 25 to 26% dinitrogen tetroxide, which freezes at 209.5 K (−82.5 °F). The freezing points of the ternary system $\text{HNO}_3/\text{N}_2\text{O}_4/\text{H}_2\text{O}$ are illustrated in Figure 2 and tabulated in Table 1. See also [8–10].

Figure 2: Curves of constant melting point in ternary system $\text{HNO}_3/\text{N}_2\text{O}_4/\text{H}_2\text{O}$. (Reproduced and modified from [7].)

Data source: [2] (see also Figure 2)

1.2.2 Boiling Point of RFNA

The boiling point of a MA with a high N₂O₄ content (54.8 mass-% HNO₃, 44.0 mass-% NO₂, 0.5 mass-% H₂O, 0.7 mass-% HF) can be extrapolated from the vapor pressure curve and was calculated as 297.8 K = 24.7 °C = 76.5 °F [11].

1.2.3 Vapor Pressure and Vapor Phase Composition of RFNA

1.2.3.1 Vapor Pressure and Vapor Phase Composition of Binary RFNA Mixtures

The high solubility of N₂O₄ in HNO₃ was already recognized very early, even before this mixture was considered as a rocket propellant, and the vapor pressure and the densities of HNO₃/N₂O₄ mixtures were measured [12]. In binary mixtures of HNO₃ and N₂O₄, if one plots the vapor pressure isotherms as a function of N₂O₄ content, as shown in Figure 17 of [13], the isotherms run flat between 35 and 95 mol-% N₂O₄ where the fluids do not mix (two-phase region) and physical properties do not change much.

Vapor pressure data for binary HNO₃/N₂O₄ mixtures are listed in Table 2. The composition of the vapor in equilibrium with binary mixtures of anhydrous HNO₃-N₂O₄-NO₂ at 273 K (0 °C) and the partial vapor pressure of the constituents of the vapor were measured with an all-glass Bourdon gauge system [14]. The composition of the liquid and vapor phases is listed in Table 3.

Table 2: Vapor pressure of RFNA (zero water content).

Mass-% NO ₂	Vapor pressure, mm Hg		Vapor pressure, kPa, at	
	0 °C	25 °C	273 K	298 K

1.2.3.2 Vapor Pressure and Vapor Phase Composition of Ternary RFNA Mixtures

At constant temperature, the vapor pressure of RFNA increases with its NO_2 concentration and decreases with increasing water content as shown in Figure 3. In this graph, the number of dashes of a line designates the NO_2 concentration, and the number of dots in the line designates the H_2O concentration (this is like trying to decipher a Morse code message), where

one dash	—	0% NO_2
two dashes	--	5% NO_2
three dashes	---	10% NO_2
four dashes	----	15% NO_2
five dashes	-----	20% NO_2
one dot	•	0% H_2O
two dots	••	10% H_2O

Figure 3: Vapor pressure of $\text{HNO}_3/\text{N}_2\text{O}_4/\text{H}_2\text{O}$ system. (Reproduced and modified from [9].)

It is difficult to measure the total vapor pressures of RFNA because part of the NO_2 vaporizes during the measurement and fills the void space. The vapor pressure is dependent on the ullage of the system. Total vapor pressures were measured in an isotenoscope for 16 acid mixtures of the ternary system nitric acid, nitrogen dioxide, and water within a temperature range of 283 to 333 K (10 to 60 °C) and with a composition range of 71 to 89 mass-% nitric acid, 7 to 20 mass-% nitrogen dioxide, and 1 to 10 mass-% water [16], also [17, 18]. Heats of evaporation were then calculated from the vapor pressure measurements for each sample for the temperatures 298, 313, and 333 K (25, 40, and 60 °C). Vapor pressure measurements depend on the size of the vapor space that has to be pressurized, since some NO_2 will be lost from the liquid in the process. The ullage of the apparatus used for these measurements was 0.46. Ternary diagrams showing isobars as a function of composition of the system were constructed from experimental and interpolated data for the temperatures 298, 313, 318, and 333 K (25, 40, 45, and 60 °C). Only the one for 298 K (25 °C) is shown in Figure 4 as an example of the temperature of most practical use.

Figure 4: Total vapor pressure isobars of nitric acid, nitrogen dioxide, and water system at 298 K (25°C). (Reproduced and modified from [16].)

Vapor pressure measurements were conducted on four HDA formulations over a temperature range of 256 to 402 K (−17 to 129°C = 1 to 264°F). The resultant values were then correlated as a function of composition and temperature and resulted in the following polynomial equation covering a temperature range from 256 to 402 K (−17 to 129°C), NO₂ concentration ranges of 43.2 to 45.6% NO₂, and water ranges from 0.4 to 1.7% H₂O [11]:

$$\log p_v = 10.7662 - 4702.28/T - 5.43556 \times 10^{-2}N + 2.5549 \times 10^{-2}W \\ + 28.5036 \frac{N}{T} + 282926/T^2$$

where log is the decadic logarithm to the base of 10, p_v is the vapor pressure in atm, T is the absolute temperature in kelvin, N is the NO₂ content in mass-%, and W is the water content in mass-%, with a standard error of estimate of $\pm 4\%$ in pressure. The vapor pressure of a nominal composition of HDA is illustrated in Figure 5. The boiling point of nominal HDA would be 297.8 K (24.7°C = 76.5°F).

Figure 5: Vapor pressure of HDA containing 44% N_2O_4 and 1% H_2O . (Chart created by Schmidt 2020, based on data from [11].)

The vapor pressure and the vapor phase composition above RFNA is directly related to the absorption of NO_2 and/or N_2O_4 into nitric acids of various water concentrations, the reversal of evaporation and dissociation. The absorption not only would be a step in the preparation of RFNA, but is also of industrial importance in the production of WFNA. The absorption rate and mechanism of NO_2 - N_2O_4 gas mixtures diluted with nitrogen absorbing into nitric acid solutions were investigated in a wetted wall column at 298 and 308 K (20 and 30 °C) [19]. It was found that N_2O_4 , which is continuously in equilibrium with NO_2 , is preferentially absorbed into diluted nitric acid as well as into concentrated nitric acid. The absorption of N_2O_4 into diluted acid is accompanied by a rapid pseudo-first-order reaction with water. Above 63% HNO_3 the absorption was found to be purely physical. The solubility of N_2O_4 in concentrated nitric acid (63%) was derived from total vapor pressure data in the system $\text{NO}_2/\text{N}_2\text{O}_4/\text{H}_2\text{O}/\text{HNO}_3$. Henry's law was valid within the range of conditions considered.

1.2.4 Density and Partial Molar Volumina of RFNA

1.2.4.1 Density of Binary RFNA Mixtures

The density of binary mixtures of HNO_3 and N_2O_4 was measured as a function of N_2O_4 content at 288 K (15 °C) [20]. Interpolated and measured density data are summarized in Tables 5 and 6. The density showed a maximum at 40% N_2O_4 (Figure 6). That figure shows densities of mixtures below and above the miscibility gap. That same report also contains data on partial molar volumina, heat of mixing, and chemical potentials of $\text{HNO}_3/\text{N}_2\text{O}_4$ binary and $\text{HNO}_3/\text{N}_2\text{O}_4/\text{H}_2\text{O}$ ternary mixtures.

Table 5: Interpolated density data for HNO₃/N₂O₄ mixtures at 288 K.

16	1.5696
18	1.5771
20	1.5846

Data source: [21]; water-free acid

The data in Table 7 agreed quite well with older data from [12], also for a water-free acid. The density of dinitrogen tetroxide solutions in 70.05%- HNO_3 changed rectilinearly depending on the N_2O_4 concentration in the solution and temperature.

1.2.4.2 Density of Ternary RFNA Mixtures

The density graph of ternary $\text{HNO}_3/\text{N}_2\text{O}_4/\text{H}_2\text{O}$ mixtures in Figure 7 is only for one given temperature ($273\text{ K} = 0^\circ\text{C}$):

Figure 7: Density in $\text{HNO}_3/\text{N}_2\text{O}_4/\text{H}_2\text{O}$ system at 273 K (0°C). (Reprinted and modified from [22] with permission from © 1955 American Chemical Society; permission conveyed through RightsLink.)

Density data of ternary $\text{HNO}_3/\text{N}_2\text{O}_4/\text{H}_2\text{O}$ mixtures under conditions of chemical equilibrium are listed in Table 8.

The density of HNO_3 solutions containing 10–27 mass-% N_2O_4 and 0–5% H_2O was determined at 273 – 323 K (0 – 50°C) and at 213 – 273 K (-60 to 0°C) with a dilatometer with an estimated probable error of 0.002 [23]. In the concentration range of N_2O_4 , C_2 , of no higher than 26 and no lower than 5%, the following equation expressed the

experimental results:

$$\rho = 1.593 + 0.37\{[C2/(C1 + C2)] - 0.2\} - aC3 - b(t - 20)$$

where $C1$ and $C3$ are the concentrations in mass-% of HNO_3 and H_2O , respectively, t is the temperature in °C, and a and b are constants with $a = 0.00536 + 0.0072 \cdot [(C2/C1) - 0.15]$, and $b = \Delta\rho/\Delta t = 0.0016$ in the -60 to $+20$ °C interval and 0.0017 in the 20 to 50 °C interval.

Density measurements were conducted on three selected HDA formulations, one described as nominal, a second with high (1.7 mass-%) water, and a third with high (54.6 mass-%) NO_2 content using a Poole-Nyberg densitometer. All the samples

contained 0.4% HF. The results were correlated through the use of a least-squares curve-fitting computer program and resulted in the following expression of density as a function of temperature and composition [24]:

$$\rho = 1.7889 - 1.8391 \times 10^{-3}t - 5.82 \times 10^{-6}t^2 - 2.420 \times 10^{-3}N - 1.750 \times 10^{-2}W$$

where ρ is the density in g/cm^3 , t is the temperature in $^{\circ}\text{C}$, N is the NO_2 content in mass-%, and W is the water content in mass-%, with a standard error of estimate of 0.0017 g/cm^3 . This equation applies to mixtures containing 43.4 to 45.6 mass-% NO_2 and 0.4 to 1.7 mass-% H_2O . The curve-fitted data from this equation are illustrated in Figure 8.

Figure 8: Density of saturated liquid HDA. (Chart created by Schmidt 2020, based on data from [11].)

Additional density data on the ternary system $\text{HNO}_3/\text{N}_2\text{O}_4/\text{H}_2\text{O}$ are in [21]. The triangular chart in Figure 9 gives lines of constant density at 308 K (35°C) for ternary mixtures of $\text{HNO}_3/\text{N}_2\text{O}_4/\text{H}_2\text{O}$ up to relatively high concentrations of either N_2O_4 or H_2O .

Determinations of the density of solutions of dinitrogen tetroxide (from 20% to boundary of separation into separate layers) in 98.2, 96.0, 94.2, and 92.2% HNO_3 at temperatures of 273, 283, and 293 K (0, 10, and 20°C) have shown that the density in the $\text{HNO}_3\text{-N}_2\text{O}_4\text{-H}_2\text{O}$ system exhibits a maximum value in the concentration range 40 to 43 mass-% N_2O_4 , whose position depends on the temperature and concentration of water in system [25, 26]. A set of equations was introduced allowing the calculation of the densities of mixtures with nitrogen tetroxide concentrations up to 10 mass-% N_2O_4 and in a temperature range of 263 to 293 K (-10 to $+20^{\circ}\text{C}$). These data can also be represented in the form of a nomograph [27].

Figure 9: Density of ternary mixtures of $\text{HNO}_3/\text{N}_2\text{O}_4/\text{H}_2\text{O}$ at 308 K (35 °C). (Reprinted and modified from [21] with permission from © 1955 American Chemical Society; permission conveyed through RightsLink.)

1.2.4.3 Volumetric and Phase Behavior of RFNA

The specific volume and compressibility of $\text{HNO}_3/\text{N}_2\text{O}_4$ and $\text{HNO}_3/\text{N}_2\text{O}_4/\text{H}_2\text{O}$ mixtures have been measured repeatedly by various laboratories over a wide range of compositions, temperature, and pressure.

The volumetric and phase behavior of four binary mixtures of nitric acid and nitrogen dioxide was measured at temperatures from 344 to 444 K (160 to 340 °F) and for pressures up to 34.4 MPa (5000 psia) [28–30]. All the data were taken at both physical and chemical equilibrium. In most cases the specific volume was determined as a function of pressure at chemical and physical equilibrium at six temperatures above 344 K (160 °F). Experimental results of one of the four mixtures are presented in Figure 10 for a HDA containing 0.4607 mass fraction nitrogen dioxide. The results presented are typical of the experimental data obtained for the other three mixtures.

These binary system data were then remeasured with improved accuracy and expanded to include up to 15% water in ternary systems [31–36].

The densities of the $\text{N}_2\text{O}_4/\text{H}_2\text{O}/\text{HNO}_3$ system with N_2O_4 mol fractions from 0 to 0.15 and H_2O mol fractions from 0.08 to 0.33 were measured at 278.15, 283.15, 288.15, and 293.15 K [37]. Figure 11 shows the density of $\text{HNO}_3/\text{N}_2\text{O}_4$ mixtures as a function of N_2O_4 content, with a constant water mol fraction of 0.02.

Figure 10: Specific volume of a HDA containing 0.4607 mass fraction nitrogen dioxide. (Reproduced and modified from [28].)

Figure 11: Density of HNO₃/N₂O₄ mixtures as a function of N₂O₄ content, with a constant water mol fraction of 0.02. (Reprinted and modified from [37], with permission from © 2011 American Chemical Society; permission conveyed through RightsLink.)

A similar graph exists for density as a function of H₂O mol fraction with a constant N₂O₄ mol fraction of 0.07. A combination of the two graphs was used to create a 3-D density graph with the N₂O₄ mol fraction plotted on the X_1 -axis and the H₂O mol fraction on the X_2 -axis (Figure 12). The excess molar volumes at 293.15 K were obtained

Figure 12: Experimental density of $\text{N}_2\text{O}_4/\text{H}_2\text{O}/\text{HNO}_3$ ternary mixtures at 293 K. (Reprinted from [37], with permission from © 2011 American Chemical Society; permission conveyed through RightsLink.)

from the experimental results for this ternary system. The experimental results were then correlated using an empirical equation. The average absolute deviations between the calculated values and experimental data were moderate. These data were obtained in support of electrochemical N_2O_5 synthesis methods to enable organic chemistry nitrating reactions (explosives synthesis) without the use of sulfuric acid.

1.2.5 Critical Point Properties of RFNA

It is very difficult to determine the critical point parameters of a mixture like RFNA or HDA because nitrogen oxide can exist in the form of either NO_2 or N_2O_4 . The critical point parameters were extrapolated from other measurable data of the constituents (Table 9) [11].

Table 9: Pseudocritical constants of HDA.

Constant	N_2O_4 present as N_2O_4	N_2O_4 present as NO_2	Extrapolated values
P_c , atm	97.4	97.1	97.2

Data source: [11]

1.2.6 Compressibility and Velocity of Sound of RFNA

The velocity of sound of a nominal RFNA composition at room temperature is 1404 m/s. Sonic velocity measurements were made in three different HDA formulations over a temperature range of 274 to 333 K (1 to 60 °C = 34 to 140 °F) under saturated liquid conditions. The resulting data were curve-fitted and resulted in the following expressions of sonic velocity as a function of temperature and composition [11]:

$$c = 2180.0 - 3.523t - 1.45 \times 10^{-2}t^2 - 14.977N - 40.6W$$

where c is the sonic velocity in m/s, t is the temperature in °C, N is the NO₂ concentration in mass-%, and W is the water concentration in mass-%. The standard errors were ±6.3 m/s. From the equation

$$\beta = \frac{1}{\rho c^2}$$

where β is adiabatic compressibility of the liquid, ρ is the density of the liquid, and c is the velocity of sound in the liquid, one can calculate the adiabatic compressibility of HDA as follows:

$$\begin{aligned} \beta = & 6.097 \times 10^{-7} - 2.9506 \times 10^{-7}t + 9.126 \times 10^{-10}t^2 + 1.718 \times 10^{-11}t^3 + 5.7924 \times 10^{-7}N \\ & + 1.727 \times 10^{-6}W + 9.808 \times 10^{-9}Nt + 2.84 \times 10^{-8}Wt \end{aligned}$$

where β is the compressibility in atm⁻¹, t is the temperature in °C, N is the NO₂ content in mass-%, and W is the water content in mass-%, with a standard error of estimate of 8.7×10^{-8} atm⁻¹.

The N₂O₄ Handbook AFRPL-TR-76-76 in the chapter “Sonic Velocity in Red Fuming Nitric Acid” listed the velocity of sound as 1379.0 m/s (4525.0 ft/s) in a sample of RFNA whose composition was 77.5% HNO₃, 20% N₂O₄, and 2.0% H₂O [3]. No temperature was given. The same value has been quoted by other sources.

1.2.7 Viscosity of RFNA

As illustrated in Figure 13, the kinematic viscosity of RFNA decreases with increasing NO₂ content in a range of 0 to 20 mass-% NO₂ and increases with increasing water content in a range of 0 to 5 mass-% H₂O. See also [22, 38].

The dynamic viscosity of two different types of RFNA is listed in Table 10. Both kinematic and dynamic viscosity data for a wide range of RFNA compositions with NO₂ content up to 51% and water content up to 5.6% at three different temperatures are presented in Table 11.

Figure 13: Kinematic viscosity in $\text{HNO}_3/\text{N}_2\text{O}_4/\text{H}_2\text{O}$ system at 273 K (0°C). (Reprinted and modified from [22] with permission from © 1955 American Chemical Society; permission conveyed through RightsLink.)

Viscosities in the $\text{HNO}_3\text{-N}_2\text{O}_4\text{-H}_2\text{O}$ system were determined for 98.2, 96.0, 94.2, and 92.2% HNO_3 at 293, 283, and 273 K (20, 10, and 0°C) [40]. The viscosity increased initially up to a maximum with an increase of N_2O_4 concentration (in the range of 39 to 43 mass-% N_2O_4) and decreased slightly with any further increase of N_2O_4 concentration. The location of the viscosity maximum was related to association processes in the mixture and varied with temperature and water concentration in the ternary system.

The viscosity of nitrogen tetroxide solutions in 70% HNO_3 remained practically unchanged (within limits of determination accuracy) with a change in N_2O_4 concen-

Table 10: Dynamic viscosity of RFNA.

tration in the solution. When the temperature dropped, the viscosity of the system rose irregularly [41]. A set of equations was introduced, allowing the calculation of the viscosities of mixtures with nitrogen tetroxide concentrations up to 10 mass-% N₂O₄ and in the range of temperatures of 263 to 293 K (–10 to +20 °C). These data can also be represented in the form of a nomograph [42].

Viscosity measurements were made on three HDA formulations over a temperature range of 274.2 to 327.5 K (1.1 to 54.4 °C = 34 to 130 °F) using a Zhukov capillary viscometer. The resulting kinematic viscosity data were correlated as a function of temperature and composition through the use of a least-squares curve-fitting computer program. The correlation included conversion to absolute viscosity using a density polynomial equation and can be represented by the following equation [11]:

$$\log \eta = 0.27546 - 470.89/T + 216430/T^2 - 1.7017 \times 10^{-2}N - 4.6580 \times 10^{-2}W$$

where $\log$ is the decadic logarithm to the base of 10, η is the absolute viscosity in centiPoise, T is the absolute temperature in kelvin, N is the NO₂ content in mass-%, and W is the water content in mass-%, with a standard error estimate of 1.6%. The absolute viscosity of a nominal HDA (44% N₂O₄, 1% H₂O) as a function of temperature is graphed in Figure 14.

Table 11: Viscosity of $\text{HNO}_3/\text{NO}_2/\text{H}_2\text{O}$ mixtures.

Viscosities and surface tensions of solutions of N_2O_4 or N_2O_5 in HNO_3 were determined at 278–293 K (5–20 °C), 0–10 mass-% N_2O_4 , or 0–20 mass-% N_2O_5 [43]. The data were fitted to empirical equations as functions of composition and temperature.

Figure 14: Absolute viscosity of saturated HDA. (Chart created by Schmidt 2020, based on data from [11]).

1.2.8 Surface Tension of RFNA

The change in surface tension with the temperature of a nominal HDA is illustrated in Figure 15. See also [44].

Figure 15: Surface tension of HDA. (Reproduced and modified from [11].)

1.2.9 Heat Transfer Coefficient of RFNA

Attempts to measure the heat transfer properties of RFNA were plagued with experimental difficulties because the heat transfer surface became coated with an insoluble residue soon after the start of the experiments and heat transfer decreased as the surface became progressively fouled [45–47]. The few data points obtained prior to this premature interruption indicated that the heat transfer to RFNA can be expressed by equations very similar to those used for WFNA [48, 49].

RFNA is not suitable as a regenerative coolant for rocket engines, but the heat transfer coefficient at the upper limit to nucleate boiling was measured and compared to that of other rocket propellants (Table 12) [50].

Table 12: Heat transfer coefficient of RFNA compared to other rocket propellants.

Coolant liquid	Heat transfer coefficient q_{ul} at 2.07 MPa = 20.4 atm, 9.1 m/s, and 310.9 K = 37.8°C inlet temperature		Heat capacity at 310.9 K = 37.8°C	
	kW/cm ²	BTU in. ⁻² s ⁻¹	J g ⁻¹ K ⁻¹	cal g ⁻¹ °C ⁻¹

Data source: [50]

The effect of iron impurity levels up to 100 ppm as Fe₂O₃ on HDA heat transfer was studied in 30 tests using resistance-heated, circular, 1/8-in.-diameter Al-6061-T6 tubes [51]. The effects of iron impurity level, propellant inlet temperature, and simulated engine shutdown were established. Coolant conditions, velocity, and pressure were characteristics of the AGENA thrust chamber tests. The chamber is regeneratively cooled with HDA. Results showed that normal nucleate boiling did not occur with either of the HDA compositions. The experimental forced convection heat transfer coefficients were unaffected by iron impurity level and exhibited increased values with increased bulk temperature. As the heat flux was increased the tube wall temperature increased much above the saturation temperature of 411 K (280 °F). Film boiling cooling was apparent up to wall temperatures of about 755 K (900 °F) when tube failure occurred. As the wall temperature increased above 422 K (300 °F), heat transfer was adversely affected by both HDA compositions at all levels of iron impurity. Tubes that had previously been operated at wall temperatures above 422 K (300 °F) with shutdown generally exhibited increased thermal resistance during the

subsequent test. This increased thermal resistance was attributed to scale formed on the inner surface of the tube. Qualitative analysis of the scale from a sectioned tube showed its composition to be inorganic sulfates and nitrates, with aluminum as the major metallic component. Test with modified HDA showed that increased thermal resistance was exhibited at each of the iron impurity levels of 10, 50, and 97 ppm. Comparison of results showed that the modified HDA exhibited about 10% lower forced convection heat transfer coefficients but somewhat higher heat flux at tube destruction than standard HDA.

1.2.10 Thermodynamic Properties of RFNA

There is substantially more need for the thermodynamic properties of RFNA than those of WFNA. Unfortunately, the thermodynamic properties of RFNA are dependent on so many variables that there are few reliable data in the literature. A detailed analysis of the enthalpies and entropies of mixing in the $\text{HNO}_3/\text{H}_2\text{O}$ and $\text{HNO}_3/\text{N}_2\text{O}_4$ systems is presented in [52].

1.2.10.1 Heat Capacity of RFNA

Heat capacity data for RFNA in Table 13 were copied from a second-hand source, but the original source of these data and the temperature range in which they are valid is not known.

Table 13: Heat capacity of RFNA.

Composition Mass-% N_2O_4	Heat capacity	
	$\text{cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$	$\text{J g}^{-1} \text{ K}^{-1}$
0	0.410	1.715
5	0.412	1.724
10	0.413	1.728
15	0.416	1.741
20	0.417	1.745
30	0.421	1.761
40	0.424	1.774
50	0.428	1.791

Data source: [53]

The heat capacity of RFNA in the range 300–422 K (80–300 °F) was determined by calorimetric measurements because it was needed to calculate the regenerative cooling capability of this oxidizer in a rocket engine [54].

1.2.10.2 Enthalpy of Formation of RFNA

The thermodynamic properties of RFNA are dependent on so many variables that there are few reliable data in the literature. In most cases the enthalpy of formation of RFNA is extrapolated from the enthalpy of formation of the pure ingredients and their heat(s) of mixing. The heat evolved when dissolving liquid N_2O_4 in HNO_3 was measured near 273 K over a range of compositions with 0 to 50 mass-% NO_2 in a Dewar flask modified for use as a calorimeter [55, 56]. Isobaric heat capacities were obtained as a side benefit while measuring the heat of solution and were found to increase from 1.71 to $1.80 \text{ J g}^{-1} \text{ K}^{-1}$ (0.41 to $0.43 \text{ cal g}^{-1} \text{ }^\circ\text{C}^{-1}$) when the N_2O_4 content was increased from 0 to 50%. The differential heat of solution of N_2O_4 in the $\text{HNO}_3/\text{N}_2\text{O}_4$ system was about 247 J/g (59 cal/g) when starting with WFNA and then dropped to 16.7 J/g (4 cal/g) when the solution was nearly saturated at 50 mass-% N_2O_4 . The integral heat of solution for making a solution of 50% N_2O_4 in HNO_3 was about 66.9 J/g (16 cal/g) of solution. The enthalpies of formation of $\text{HNO}_3/\text{NO}_2/\text{H}_2\text{O}$ mixtures containing 0 to 50 mass-% NO_2 at 273 K (0°C) were tabulated [57].

The heat of solution of N_2O_4 in HNO_3 was estimated to be near -6.53 kJ/g-mol (-1.56 kcal/g-mol) N_2O_4 . The small amount of HF that is also added as corrosion inhibitor has only a minor effect on the heat of formation of the IRFNA or HDA mixture.

One undocumented secondary source of data listed the standard enthalpy of formation of RFNA (84% HNO_3 , 14% N_2O_4 , 2% H_2O , average molecular mass 75.016 g/mol) (ΔH_f^{298}) as $-638.1 \text{ cal/g} = -47.868 \text{ kcal/mol}$.

The heat of formation of HDA (with a nominal composition of 54.8% HNO_3 , 44.0% N_2O_4 , 0.5% H_2O , 0.7% HF) was estimated using the additive heats of formation of the components and their heats of solution with each other and gave $+181.2 \pm 3.3 \text{ kJ/100 g}$ ($+43.3 \pm 0.8 \text{ kcal/100 g}$) [11]. The empirical formula of such a mixture would be $\text{N}_{1.82606}\text{H}_{0.96015}\text{O}_{4.54953}\text{F}_{0.03499}$.

Red fuming acid data listed in PEPCODED.DAT with 14% NO_2 have the gross formula $\text{H}_{151}\text{N}_{165}\text{O}_{471}$ and an enthalpy of formation of $-654 \text{ cal/g} = -2736 \text{ J/g}$ and a density of $0.0567 \text{ lb/in.}^3 = 1.569 \text{ g/cm}^3$ [58]. A similar acid with 20% NO_2 has the gross formula $\text{H}_{85}\text{N}_{114}\text{O}_{314}$ and an enthalpy of formation of $-544 \text{ cal/g} = -2276 \text{ J/g}$. The related data file JPLCODED.DAT (1988) uses an RFNA with the gross formula $\text{H}_{1.56470}\text{N}_{1.63390}\text{O}_{4.72100}$ and an enthalpy of formation of $-638.1 \text{ cal/g} = -2667 \text{ J/g}$.

1.2.10.3 Heat of Evaporation of RFNA

The heat of evaporation of RFNA or HDA is difficult to determine because vapor pressure is mostly due to the NO_2 , and the composition of the vapor phase would change with increasing temperature. To predict the heat of evaporation, one needs to know vapor-phase composition measurements for the vapor space above RFNA or

HDA. The heat of evaporation can be calculated from vapor pressure measurements using the Clausius-Clapeyron equation, but it would be valid only for evaporation at the boiling point at atmospheric pressure. Approximating calculations yielded a value of 7.00 kcal/mol vapor at the normal boiling point 297.8 K (24.7 °C = 76.5 °F) assuming the vapor is mostly NO₂.

The heats required to vaporize 1 mol of the equilibrium vapor mixtures from infinite amounts of the liquid samples were estimated from the slopes of vapor pressure curves. The differences in these heats of evaporation among samples of different composition at the same temperature were not very large; the heats ranged from 36.0 to 42.1 kJ/mol (8.6 to 10.07 kcal/mol) at 298 K (25 °C) and from 34.8 to 40.7 kJ/mol (8.320 to 9.740 kcal/mol) at 333 K (60 °C) [16–18].

1.2.11 Optical, Electrical, and Magnetic Properties of RFNA

1.2.11.1 Raman Spectra of RFNA

The Raman spectra of solutions of dinitrogen tetroxide in nitric acid led to the conclusion that the dinitrogen tetroxide molecule, in dilute solution in nitric acid, is almost completely disassociated, partly homolytically, but chiefly heterolytically, as follows [59]:

The frequency of the nitrosonium ion is usually found at about 2300 cm⁻¹, though the value varies slightly with the conditions of solvation. The value 2240 cm⁻¹, obtained in nitric acid, is, however, outside the usual range of variation, and it is shown to arise from a modification of the nitrosonium ion by some specific molecular interaction. The nitrogen dioxide molecule is assumed to form a molecular compound NO⁺•NO₂, held together by a partly homopolar but mainly electrostatic one-electron bond.

A Raman spectral study of solutions of N₂O₄ and N₂O₅ in anhydrous and aqueous HNO₃ provided a more detailed knowledge of the species present in these solutions and to assess the applicability of Raman spectroscopy as an analytical measurement technique [60]. Solutions of N₂O₄ in HNO₃ showed evidence of the presence of the associated species, 3NO⁺•NO₃⁻ (also written N₄O₆⁺²), which had been identified previously in a solid compound. The effects of H₂O on the spectra of these solutions were also examined.

The Raman spectra of HNO₃-containing NO₂ have been analyzed on liquid and solid surfaces. The Raman spectra of HNO₃ solutions containing N₂O₄ have been partly reinterpreted in terms of contributions from HNO₃•N₂O₄ and N₂O₄•NO₃⁻ adducts [61]. Some of such adducts may form in highly polluted atmospheres.

1.2.12 Electrical Conductivity of RFNA

The electrical conductivity of the binary system HNO_3/NO_2 is dependent on the NO_2 content. At 273 K and atmospheric pressure, nitrogen dioxide (dinitrogen tetroxide) is miscible with nitric acid only above 0.48 mass fraction HNO_3 . Below 0.48 mass fraction HNO_3 , a second liquid phase appears containing less than 0.1 mass-% HNO_3 . The specific conductance of this latter phase is small, being less than $7 \times 10^{-6} \text{ Ohm}^{-1} \text{ cm}^{-1}$ at 273 K. Between 0.72 and 1.00 mass fraction HNO_3 the conductance of the system decreased with increasing concentrations of acid [62]. This behavior agrees with studies of Raman spectra of solutions of nitrogen dioxide in nitric acid where nitrosonium ions (NO^+) and nitrate ions (NO_3^-) have been identified. The dinitrogen tetroxide undergoes homological dissociation and ionizes to give these ionic species according to the reaction equation

This ionization caused the increase in conductance observed when nitrogen dioxide was added to HNO_3 . At mass fractions of HNO_3 below 0.72, a decrease in HNO_3 concentration resulted in a decrease in conductance until the phase boundary was reached (Figure 16).

Figure 16: Specific conductance of nitric acid/nitrogen dioxide at 273 K and atmospheric pressure. (Reproduced and modified from [63].)

Table 14: Electrical conductivity of anhydrous RFNA at 273 K (0 °C).

Mass fraction		Specific electrical conductivity, $\text{Ohm}^{-1} \text{cm}^{-1} \times 10^2$
NO_2	HNO_3	
0.144	0.856	12.9
0.200	0.800	14.6
0.249	0.751	15.2
0.293	0.707	15.3
0.358	0.642	14.7
0.419	0.581	13.6
0.471	0.529	12.5
0.511	0.489	11.7
0.548	0.452	10.7

Data source: [63]

The electrical conductivity of the ternary system $\text{HNO}_3/\text{NO}_2/\text{H}_2\text{O}$ is dependent on both NO_2 and water content (Table 14). Electrical conductance measurements present a possible analytical tool for determining the composition of RFNA or WFNA. It is necessary to determine the concentration of only one species in the system by another physicochemical method such as the measurement of transmittance with a spectrophotometer. The nitrogen dioxide or water concentration can be determined by transmittance measurements in the visible region or the IR region, respectively. These measurements together with the conductance measurements bracket no more than two values of composition. Figure 17 shows smoothed curves of constant specific conductance as a function of composition for nitric acid weight fractions greater than 0.80 in a ternary composition diagram.

Figure 17: Curves of constant specific conductance in nitric acid-nitrogen dioxide-water system at 273 K and atmospheric pressure. (Reproduced and modified from [63].)

Table 15, which gives a very detailed list of electrical conductivity of $\text{HNO}_3/\text{NO}_2/\text{H}_2\text{O}$ mixtures at 273 K and 101 kPa, is suitable for the quick look-up of data to accurately correlate composition and conductivity.

Table 15: Electrical conductivity of HNO₃/NO₂/H₂O mixtures at 273 K and 101 kPa.

Mass fraction HNO ₃	Specific electrical conductivity, Ohm ⁻¹ cm ⁻¹ × 10 ²

1.2.13 Solubility and Miscibility with Mixtures of RFNA

Solubility data are for gaseous or solid compounds that dissolve in nitric acid. Miscibility data are for other liquids that are added to nitric acid to improve its properties as a rocket propellant.

Solubility and miscibility are a chemical phenomenon, but solubility numbers for various compounds in HNO_3 should be summarized under physical properties. Some phase diagrams indicate compound formation. Not all mixtures lead to HNO_3 -based oxidizers with more desirable properties than pure HNO_3 .

1.2.13.1 Miscibility in $\text{HNO}_3/\text{H}_2\text{O}$ Binary System

Inevitably, whether or not one wants it, WFNA will contain varying amounts of water as a byproduct carried over from its production, moisture absorbed from the atmosphere, or water formed during decomposition of HNO_3 .

1.2.13.2 Miscibility in HNO_3/NO_2 Binary System

Freezing-point measurements in the system $\text{HNO}_3/\text{N}_2\text{O}_4$ indicate that at a molar ratio of $\text{N}_2\text{O}_4 : \text{HNO}_3 = 1 : 2$ a solid additive compound is formed. Nitric acid and dinitrogen tetroxide at 273 K are miscible only in the composition range from 0 to 52 and 99.6 to 100 mass-% N_2O_4 [15]. In between there exists a miscibility gap that limits the choices of RFNA compositions for various propulsion applications.

As shown in Figure 18, the mixtures in a range between these numbers separate into two immiscible phases, which would be highly undesirable for the use of RFNA as a rocket propellant. A critical mixing temperature exists at 334 K (61 °C) and 68.6 mass-% N_2O_4 . Above this point the two liquids are miscible over the entire range of mixture ratios (although the system must be pressurized to prevent boiling).

The temperature for the phase separation of N_2O_4 was measured in $\text{HNO}_3\text{-H}_2\text{O}$ systems containing 69.9–99.99% HNO_3 [64]. The critical phase separation (“demixing”) temperature changes with the proportion of N_2O_4 in the mixture and reaches a maximum value. This critical value changes with the HNO_3 concentration in the $\text{HNO}_3\text{-H}_2\text{O}$ system and reaches a minimum value of 315 K (42 °C), with the eutectic containing 90.5% HNO_3 .

The ternary system $\text{HNO}_3/\text{NO}_2/\text{H}_2\text{O}$ has a eutectic point at a composition of 4% H_2O and 17% NO_2 with a freezing point of 195 K (–78 °C).

The liquid-liquid and solid-liquid equilibrium phase boundaries and liquid-liquid and solid-liquid equilibrium data for the $\text{N}_2\text{O}_4/\text{HNO}_3$ system were measured by a cloud point method at 258.2–281.2 K [65, 66]. The critical points and the solubility of dinitrogen tetroxide in nitric acid and the solubility of nitric acid in dinitrogen tetroxide showed that with an increase in temperature, the two-phase area shrank and the solubilities of dinitrogen tetroxide in nitric acid and nitric acid in dinitrogen tetroxide increased, as expected. The addition of dinitrogen pentoxide to RFNA would create an even more powerful oxidizer. Addition of dinitrogen pentoxide affects the miscibility gap between N_2O_4 and HNO_3 .

Figure 18: Miscibility of nitric acid and dinitrogen tetroxide. (Reproduced and modified from [29, 15].)

Dissolving N_2O_4 in HNO_3 is not only a physical solution process but involves shifting some of the equilibria that otherwise would lead to the decomposition of HNO_3 [67].

1.2.13.3 Solubility of Gases in RFNA

The solubility of gases in RFNA is of practical interest for several reasons: **(1)** oxygen may have formed as a result of continuing decomposition of HNO_3 , although the addition of H_2O and NO_2 to the equilibrium mixture will suppress further decomposition, and **(2)** pressurant gases will dissolve in the oxidizer and cause cavitation during pumping or loss of performance.

Although dissolving a gas (here identified by the subscript i) in a liquid solvent (identified by the subscript j) is a physical process where no chemical changes are involved, the process

can be expressed by an equilibrium constant like those used for chemical reactions:

$$K = \frac{\text{ppm}_i}{P} = 10^6 M_i \frac{X_i}{M_j} P_i$$

where M_i and M_j are the molecular masses of the gas and the solvent, X_i is the mol fraction of the gas in the solution, and P_i is the pressure above the solution (in units of atmospheres). K is temperature dependent, and a plot of $\log K$ vs. $1/T$ gives a linear correlation like an Arrhenius curve:

$$\log K_i = \frac{A}{T} + B$$

where A and B are dimensionless constants tabulated in Table 16 [68].

Table 16: Gas solubility equation constants for gases dissolving in IRFNA.

Gas	A	B	Solubility at 1 atm (ppm)	
			at 273 K	at 298 K
He	-232	0.7121	0.7	0.8
N ₂	-1364	6.3730	24.0	62.8
CO ₂ ^a	+787	1.241	13300	7600

^a Estimated by similarity method

Data source: [68]

1.2.13.4 Solubility of Oxygen in RFNA

The solubility of O₂ in HNO₃ mixtures was determined from 308 to 343 K (35 to 70 °C) and for pressures up to 2.13 MPa (21 atm). The solubility increased with the temperature. Contrary to the solubility trend of oxygen in other solvents, the solubility of oxygen in nitric acid increased with temperature, as indicated by the change in Henry's law coefficient

$$\text{CO}_2 = \alpha \text{PO}_2$$

The solubility of oxygen in nitric acids of varying compositions is summarized in Table 17.

Table 17: Solubility coefficient of oxygen in nitric acid and mixtures containing water and/or nitrogen dioxide.

Constituents	Composition	Temperature		Solubility coefficient α
	Mass fraction	K	°C	
HNO ₃	1.00	310.8	37.7	5.55
HNO ₃	1.00	327.5	54.4	5.80
HNO ₃ /NO ₂	HNO ₃ 0.85/NO ₂ 0.15	310.8	37.7	3.60
HNO ₃ /NO ₂	HNO ₃ 0.85/NO ₂ 0.15	310.8	37.7	3.78
HNO ₃ /NO ₂	HNO ₃ 0.85/NO ₂ 0.15	327.5	54.4	3.84
HNO ₃ /NO ₂	HNO ₃ 0.85/NO ₂ 0.15	327.5	54.4	3.86
HNO ₃ /H ₂ O	HNO ₃ 0.94/H ₂ O 0.06	310.8	37.7	4.16

1.3 Chemical Properties of RFNA

Calculations were performed to determine the structures, energetics, and spectroscopy of atmospherically relevant complexes that might also occur in RFNA, such as (HNO₃)•(NO₂), (HNO₃)•(N₂O₄), (NO₃⁻)•(NO₂), and (NO₃⁻)•(N₂O₄) [71]. The binding energies indicated that three of the four complexes are quite stable, with the most stable (NO₃⁻)•(N₂O₄) possessing a binding energy of almost 58 kJ/mol (14 kcal/mol). Vibrational frequencies were calculated for use in detecting the complexes by IR and Raman spectroscopy. An attenuated total reflectance-Fourier transform infrared (ATR-FTIR) experiment showed features at 1632 and 1602 cm⁻¹ that were attributed to NO₂ complexed to NO₃⁻ and HNO₃, respectively. The electronic states of (HNO₃)•(N₂O₄) and (NO₃⁻)•(N₂O₄) were investigated using an excited state method, and it was determined that both complexes possess one low-lying excited state that is accessible through absorption of visible radiation. Evidence for the existence of (NO₃⁻)•(N₂O₄) was obtained from UV/vis absorption spectra of N₂O₄ in concentrated HNO₃, which showed a band at 320 nm that was blue-shifted by 20 nm relative to what is observed for N₂O₄ dissolved in organic solvents.

1.3.1 Analysis of RFNA

Analytical methods are needed for the determination of HNO₃ assay and H₂O, NO₂, HF contaminants and additives in IRFNA [72]. In the United States, RFNA for rocket propellant applications must meet the requirements of Military Specification MIL-PRF-7254G – Propellant, Nitric Acid [73], but there is no specification for WFNA. The WFNA

that is used to make RFNA is not covered by a specification of its own. There are three types of RFNA called out in that specification (Table 18). In Type IIILS, the LS stands for limited storage. The HDA Type IV was added to the specification as an amendment in 1972 and made permanent in 1997. The N_2O_4 used for making Type IV HDA must meet the requirements of MIL-PRF-26539F – Propellants, Dinitrogen Tetroxide, MON-1.

Table 18: Composition of RFNAs as specified by MIL-PRF-7254G.

Constituent	Unit	Type of IRFNA				Test method
		Type IIIA	Type IIIB	Type IIILS	Type IV High Density	
HNO_3	Mass-%	81.6–84.9	81.7–84.9	83.7–86.4	52.7–57.4	By difference
NO_2	Mass-%	14 ± 1	14 ± 1	14 ± 1	44 ± 2	Cerimetric titration
HF	Mass-%	0.7 ± 0.1	0.7 ± 0.1	0.7 ± 0.1	0.7 ± 0.1	Fluoride-specific ion electrode
H_2O	Mass-%	1.5–2.5	1.5–2.5	0.5 max.	0.5 max.	IR spectrophotometric at $1.4 \mu\text{m}$
Fe_2O_3	Mass-%	not specified	not specified	0.0015 max.	0.002 max.	Colorimetric at 248 nm, in HCl-dissolved solids residue
Solids, max. as nitrates	Mass-%	0.10	0.04	0.04	0.04	Gravimetric
Specific gravity, at 289 K = 60 °F	g/cm ³	1.564–1.575	1.564–1.575	1.572–1.582	1.642–1.652	Hydrometer

The chemical composition of RFNA can change slowly with extended storage, although the changes are not as fast or as dramatic as with WFNA. Nevertheless, it is important to analyze RFNA at the point of delivery and again before it is filled in a rocket propulsion system. Since RFNA has been fielded in several prepackaged missiles, selected units are returned from the field as a regular surveillance program to determine the useful lifespan under real-life conditions. The main parameters analyzed are the water and NO_2 content, since these will affect the ignition delay with hypergolic fuels. See also [74–76].

1.3.1.1 Determination of Water Content in RFNA

A method for determining water in WFNA or RFNA is volumetric titration using Karl Fischer reagent [77, 78]. This method can be used in RFNA containing up to 15% NO_2 , and the standard deviation is 0.052% absolute.

Simplified go/no go indications of RFNA samples can be obtained by electric conductometric methods. One of these methods [79, 80] measured the conductivity at constant temperature, one sample as is and a second sample after saturating it with potassium nitrate.

The electrical conductivity of the ternary system $\text{HNO}_3/\text{NO}_2/\text{H}_2\text{O}$ is dependent on both NO_2 and water content [62]. Thus, the method by itself cannot give both the NO_2 and H_2O content. The method must be combined with another method to obtain both numbers.

The water analysis method recommended in MIL-PRF-7254G first obtains the absorption spectrum of the sample between 1500 and 1350 nm versus CH_2Cl_2 , both contained in 5-mm cells, then measures the absorption at 1404 nm, which is specific for water, while the absorption at 1440 nm is mostly that of HNO_3 . A calibration curve is generated from solutions of water in acetonitrile with known H_2O concentrations.

1.3.1.2 Determination of NO_2 Content in RFNA

The NO_2 content of RFNA can be determined spectrophotometrically at 425 or 500 nm in a thermostatted spectrophotometer as long as there are no other colored contaminants [81–83]. A calibration curve can be best prepared from freshly prepared samples with known NO_2 contents. Water contents must be kept similar for both calibration and actual samples. The photometric method has also been used to determine the degree of dissociation of NO_2 and HNO_3 in RFNA.

The optical absorbance of solutions of nitrogen dioxide in nitric acid was measured at 273 K (0 °C) and 1 atm using light at a wavelength of 425 nm to study the ionization occurring in solutions [82–84]. The results indicated that in nitric acid solutions containing less than 1% nitrogen dioxide, the nitrogen dioxide is about 70% ionized into nitrosonium ion NO^+ , whereas the nitric acid is about 5% ionized into nitronium NO_2^+ ions.

A dual-band spectrophotometer has been developed especially for RFNA analysis that can analyze both H_2O and NO_2 : First the H_2O absorption at 1.423 μm and then the NO_2 absorption at 480 nm is measured and compared to absorption values obtained from calibration curves [85]. The accuracy is $\pm 0.064\%$ for water and $\pm 0.25\%$ for NO_2 . The sample must be free of iron nitrate or other colored contaminants that might interfere with NO_2 determination.

For the determination of N_2O_3 , NO_2 , and HNO_2 in nitric acid by volumetric methods, one can first titrate total acid acidimetrically and then titrate the oxidizable species by manganometric titration [86].

The method for nitrite analysis recommended in MIL-PRF-7254G dissolves an IRFNA sample in excess of 0.5-N NaOH under exclusion of air, then reacts an acidified aliquot with an excess of 0.1-N acidic ceric ammonium hexanitrate solution sufficient to react the nitrite ion, and then back-titrates with acidic 0.05-N ferrous ammonium sulfate solution with potentiometric end point indication.

Mass spectrometric analysis of WFNA or RFNA may be very accurate and identify many species, but it is not practical for field use [87]. This method would be used only to identify unusual contaminants or for kinetic studies. For other analytical methods for RFNA see also [88–92].

The addition of dinitrogen pentoxide to RFNA creates a more powerful oxidizer and nitrating agent, so its composition must be analyzed before additional testing is done with this oxidizer [93]. The concentrations of N_2O_4 and N_2O_5 in nitric acid can be measured by chemical titration or NMR [94]. Both methods are in agreement and accurate. N_2O_4 assay titrations using cerium(IV) sulfate as the oxidant were more accurate than those using potassium permanganate as the oxidant.

Some chemical supply companies offer RFNA described as “ HNO_3 , >90%, 5–10% dissolved oxides as N_2O_3 .” This description may not be accurate because if the acid contained N_2O_3 instead of $\text{NO}_2/\text{N}_2\text{O}_4$, it would be blue-green and not red.

1.3.2 Thermal Stability and Decomposition of RFNA

The thermal stability of RFNA during sudden heating (as in a regenerative cooling jacket in a rocket engine) is sufficiently high and will not cause any chemical changes between the start of the heating and injection into the combustion chamber. Concern is only for the liquid that may remain trapped in the cooling jacket after the engine shuts down and heat soaks from the hot wall into the remaining structure of the engine. In this regard, RFNA is more stable than WFNA because it is already close to the equilibrium composition in the $\text{HNO}_3/\text{NO}_2/\text{H}_2\text{O}$ system [95, 96].

Dinitrogen tetroxide and/or water has been added to WFNA to retard the troublesome oxygen evolution and potential overpressurization of tanks during storage. The equilibrium decomposition pressure of samples of $\text{HNO}_3/\text{H}_2\text{O}$ mixtures containing 2.5 and 5.0 mass-% water and of HNO_3/NO_2 mixtures containing 7.5 and 15.0 mass-% nitrogen dioxide were determined between 358 and 423 K (85 and 150 °C) and at vapor volume to total apparatus volume ratios varying from 0.05 to 0.8 [97]. The decomposition measurements were carried out in a glass tube in a high-pressure apparatus under isochoric conditions and with continuous stirring. The experimental data were then presented graphically a) as plots of equilibrium pressure vs. ratio of vapor volume to total volume, V_G/V , at constant temperature and b) as plots of the equilibrium pressure vs. the specific volume of the mixture at constant temperature. By appropriate cross plots of the data, a series of diagrams showing the equilibrium pressure vs. temperature at constant V_G/V ratios for integral values of initial water and nitrogen dioxide content were prepared and high-temperature data were extrapolated to 298 K (25 °C). The kinetics of decomposition of nitric acid was studied by analyzing available pressure-time rate data for different V_G/V values and in a temperature range of 349 to 373 K (76 to 100 °C). Rate measurements were also carried out in the presence of excess nitrogen dioxide and water for different V_G/V values at 358 K (85 °C) and with excess

oxygen at an initial pressure of 3.1 MPa gauge (454 psig) and at 349 K (76 °C). Under the conditions of the investigation, the decomposition of nitric acid was believed to be a homogeneous liquid-phase reaction. The rate of decomposition can be represented satisfactorily by the equation

$$\frac{dP}{dt} = Ae^{B(P_{\infty} - P)}$$

where P_{∞} = equilibrium pressure, t = time, e = base of natural logarithms, and A and B are constants. This equation held accurately over 80% of the reaction. The initial fast rate was followed by a slower apparent-first-order rate with respect to time. The initial rates were (a) unaffected by addition of up to 15% nitrogen dioxide or by excess oxygen at an initial pressure of 3.1-MPa gauge (454 psig) at 349 K (76 °C) and (b) lowered considerably by the addition of small amounts of water. The specific first-order rates were increased by excess nitrogen dioxide and oxygen but were lowered by added water. The experimental energy of activation was found to be 125.5 kJ/mol (30 kcal/mol), independent of the V_G/V ratio. The preexponential factor for the Arrhenius equation was 10^{14} s^{-1} .

Later experiments confirmed that (1) the pressure, which is primarily due to the oxygen formed as a result of the decomposition, increased with an increase in temperature and with a decrease in the V_G/V ratio, (2) the pressure was markedly reduced by the addition of nitrogen dioxide and (or) water, particularly at the lower temperatures, and (3) the V_G/V ratio had a very great influence on the value of the equilibrium pressure of mixtures high in nitric acid content, but this influence diminished with the addition of nitrogen dioxide and water and became relatively insignificant in mixtures containing more than 20% of additive (nitrogen dioxide plus water). On a weight basis, water was more effective in reducing the pressure than nitrogen dioxide.

Thermal stability tests starting with WFNA and RFNA with widely varying compositions showed that the ternary diagram can be subdivided into three stability regions:

- A. Decomposition with resulting pressure increase due to oxygen evolution
- B. Stable, but only while maintaining increased oxygen pressure
- C. Stable under most conditions

The compositions of the liquid phase at physicochemical equilibrium at 358 K (85 °C) and the three regions of (in)stability were plotted on a triangular diagram (Figure 19) [98]. None of the equilibrium mixtures contained more than about 91% nitric acid, indicating that acids of this strength and above were unstable and would decompose spontaneously at this temperature. On the other hand, ternary mixtures containing 80% nitric acid and more than 6% water were found to be stable. Compositions between these two extremes were stable only under an oxygen pressure of 0.34 to 10.3 MPa (50 to 1500 psia).

The ultimate decomposition pressures at equilibrium if WFNA or RFNA with low N_2O_4 and H_2O contents is stored at 358 K (85 °C) in a hermetically closed system

Figure 19: Stability regimes of RFNA at 358 K (85 °C). (Reproduced and modified from [98].)

with only 15% ullage were calculated and displayed in a ternary diagram, Figure 20 [96–99]. As shown in this graph, the decomposition pressures developed at the end of the test can be quite destructive.

The saturation pressure of NO_2 dissolved in HNO_3 with 3% H_2O reaches atmospheric pressure once the NO_2 concentration is increased beyond 16% NO_2 . For this reason, it is not practical to increase the NO_2 concentration beyond 16% NO_2 because the composition of the acid would change each time the liquid is transferred from one container to another or the vapor space is vented. The NO_2 saturation pressure could be decreased slightly by adding more water, but that is not desirable because it causes a loss of rocket performance of the resulting oxidizer mixture. These calculations are of interest not only in the handling and storage of nitric acid but also in the manufacture of concentrated nitric acid from liquid nitrogen dioxide, water, and oxygen under pressure, where the same equilibrium is approached from the other side.

The addition of HF as a corrosion inhibitor to RFNA to make IRFNA does not change the thermal and storage stability of the acid, other than preventing the leaching of contaminants that might catalyze the decomposition reaction. The thermal stability of IRFNA is discussed in Section 2.3.2.1.

A maximum-density HDA that is stable enough to survive the sterilization heating of interplanetary spacecraft may contain 43.9% NO_2 and 56.03% HNO_3 [100]. The

Figure 20: Decomposition pressure (in atm) of $\text{HNO}_3/\text{NO}_2/\text{H}_2\text{O}$ mixtures at 358 K (85 °C) in a container with 15% ullage. (Reproduced and modified from [99].)

addition of 0.1–1% HF may reduce the corrosion of metals. This composition was also called maximum-density fuming nitric acid (MDFNA).

1.4 Compatibility with and Corrosion of Materials in RFNA

Several metals and alloys were tested to determine their rates of corrosion in two types of RFNA and one type of MA [101]. Several stainless steels and Duriron exhibited good resistance to corrosion by concentrated nitric acids; aluminum alloys were more extensively attacked, Haynes-Stellite alloys and chromium were only slightly corroded, and tin, gold, and tantalum exhibited very good resistance to corrosion, even at elevated temperatures. Corrosion rates in MA were lower than in the other nitric acids for most of the metals tested (Table 19). In general, corrosion rates in 16 and in 6.5% NO_2 RFNA were similar. A limited number of experiments with WFNA (containing less than 0.5% NO_2) indicated further that the corrosion rates of metals were not significantly different in fuming nitric acids with various concentrations of nitrogen dioxide.

Table 20 gives the stagnant corrosion rates of CRES-304 in 6.5% NO₂ RFNA for six different temperatures.

The primary advantages of Type IIIA acid with regard to storage stability, low freezing point, and less corrosion were sufficient to justify its use in rocket propulsion systems slated to be developed in the US shortly after World War II for tactical use. The use of 17-7PH with Type IIIA acid was considered questionable [102]. Most rocket engine construction materials are equally adaptable to Types I and IIIA acids. Design criteria (combustion, injection, pumps, and cooling jackets) appear to be equally adaptable to Types I and IIIA acid. The differences in vapor pressure, density, and heat capacity must be considered in systems design.

The corrosion, ignition reactions, and stress-corrosion cracking of titanium and its alloys resulting from storage in fuming nitric acid were studied [103]. The metal samples were stored in the liquid and vapor phases of various concentrations of the HNO₃-NO₂-H₂O system for periods of time ranging from 1 h to 90 d at temperatures ranging from room temperature to 344 K (71°C). The susceptibility to ignition reactions, the tendency toward stress-corrosion cracking, and the corrosion rates of the metal were studied as a function of the chemical composition and temperature of the fuming nitric acids. In particular, the corrosion-time relationships of two titanium alloys in anhydrous RFNA (20% NO₂) over a temperature range of 298 to 344 K (25 to 71°C) were determined. The corrosion rates of Ti-6Al-4V in RFNA with 0, 10, or 20% NO₂ after 1 week at 327 K (54°C) were 8.16, 20.76, or 96.83 mil/year (1 mil = 0.001 in.). The samples in 10 or 20% NO₂ RFNA were sensitive to ignition when scratched, but those in 0% NO₂ = WFNA were not. The addition of 1 to 2% water significantly reduced the corrosion rates. The addition of hydrofluoric acid did not change the corrosion behavior of titanium in RFNA [104, 105].

Tests on A70 commercial titanium and Ti-7% Mn alloy C110M indicated that sporadically rapid attack in RFNA may be associated with limited air supply in the test container. Evidence was found indicating that sporadically observed rapid attack on titanium in RFNA may, in some cases, be associated with a limited air/oxygen supply

in the test container [106]. Additions of air, oxygen, and certain salts resulted in noticeable corrosion inhibition. Attack in the uninhibited acid was found to be largely intergranular. In the case of a two-phase alloy, the beta phase was removed preferentially, leaving a finely divided pyrophoric deposit of the alpha structure. A commercial grade of RFNA was used that had a specific gravity of 1.59 to 1.60 g/cm³ and a nominal composition of 20% NO₂, 78% HNO₃, and 2% H₂O. The WFNA consisted of 90% HNO₃ and 10% H₂O and had a specific gravity of 1.49 to 1.50 g/cm³. A possible mechanism was proposed for the observed breakdown in passivity.

Storage tests to determine the effectiveness of inhibition by oxygen indicated no inhibition of titanium corrosion by oxygen but confirmed the inhibiting effect of water content of 1 to 2 mass-% in fuming nitric acid [107]. The addition of water alleviates the tendency of titanium, when exposed to anhydrous RFNA, toward ignition reactions and stress cracking. In these tests, which lasted 28 d at 303 K (30 °C), the samples investigated were 1/2-in. squares (0.020 in. thick) of commercially pure (CP) titanium (75A) and a binary 8%-manganese alloy (C110M). When analyzing for leached metals in solution, the Ti concentrations in the acid offloaded from the Ti CP were very small (0.01–0.15% Ti), but in the Ti-Mn alloy, both metals were leached in substantial quantities (0.07–0.88% Ti). The metal after corrosion in anhydrous RFNA (20% NO₂) was pyrophoric.

Static corrosion tests were performed to evaluate candidate materials being considered for use with standard HDA [108, 109]. HDA contained 53–54% HNO₃, 44–45% NTO, 0.2% H₂O, and 0.7% HF. The NTO used for making HDA contained 1 mass-% NO and was green, so it should have been designated as MON-1. The tests were performed at temperatures and times representative of anticipated service conditions for each material. Fifty-nine candidate rocket engine materials were screened through corrosion tests with standard HDA. This included 19 tests for a total of 7 d at 322 K (120 °F), 5 tests for a total of 6 h at 378 K (220 °F), and 38 tests for a total of 60 d at 305 K (90 °F). In addition to studying duration and temperature effects, the tests provided comparisons between parent metals, welds, and galvanic couples. In most cases, data were obtained for exposure to liquid and vapor. With few exceptions, S/V (surface of metal/volume of acid) was 1.0, which is intermediate between conditions in large tanks and small lines. The objective of these analyses was to provide an explanation for current test results and a basis for future tests with inhibitors other than HF. Measurements and observations were made both for changes in the acid and the material. This included chemical analyses and corrosion rates calculated from changes in mass. Based on the results, the materials were ranked in one of four categories, ranging from satisfactory for general use to unsatisfactory. Class I materials were considered satisfactory for general use in contact with the propellant tested. Other classes were restricted in usage. Several aluminum alloys fell in the former category. Stainless steels appeared good for limited use. Only three stainless steel samples exhibited a Class I rating, and this only at 305 K (90 °F). Results are shown in Table 21, where X denotes an acceptable

operating condition for 7-d use and the Roman numerals indicate marginal material classes. It was recommended that compounds containing fluorine and phosphorus be evaluated as inhibitors.

A study of the influence of dissolved corrosion products from CRES-347 or Al-6061 on the phase separation in HDA, containing 52.7–57.4 mass-% HNO_3 and 44 ± 2 mass-% N_2O_4 showed that the presence of two liquid phases could be responsible for flow irregularities, particularly if one of these phases is of high viscosity as a result of a high concentration of dissolved corrosion products [110]. For any given amount of corrosion products in solution, it is important to determine the exact liquid composition at which a second phase appears. In searching for the best method for detection of phase separation in $\text{HNO}_3/\text{N}_2\text{O}_4$ mixtures, changes in electrical conductivity were found to provide a sensitive and accurate method. Experiments showed a considerable decrease in corrosion rate by uninhibited HDA as the concentration of N_2O_4 was increased (Figure 21).

Figure 21: Dependence of corrosion rate of CRES-321 on N_2O_4 concentration in HDA. (Reproduced and modified from [110].)

The selection of materials for the safe handling of RFNA requires special considerations, in particular for welded stainless steels, where the heat-affected zone becomes more susceptible to corrosion due to carbide precipitation [111]. See also [112].

The corrosion rate of nickel-silicon alloys in RFNA as a function of the silicon content was shown to have two extreme points: a maximum at a Si content of 5% and a minimum at 10% Si [113]. Alloying of Ni-15% Cr alloys with silicon monotonically lowered their corrosion rate. Corrosion rates were correlated to the electrochemical potentials of Ni/Cr and Ni/Cr/Si alloys.

A procedure for corrosion investigation of stainless steels and heat-resistant alloys in RFNA at high temperatures was developed and corrosion rate data were obtained for stainless steels and heat-resistant alloys at 323–723 K (50–450 °C) [114]. Corrosion rate data were obtained for (Russian designations) EI654, 12Kh18N10T, Kh28VI, 15Kh18N12S4TYu, and 95Kh18 steels and EI703 alloy. It was found that the corrosion rate increased sharply with the temperature while the system was in the liquid phase. Then at 573–723 K (300–450 °C) the corrosion rate slowed down, and scale coated the metal surface. The apparatus for studying electrochemical behavior of metals in a corrosive medium at high temperatures consisted of glass with metal electrodes. Anodic potentiostatic curves of stainless steel in RFNA showed that the rise in temperature reduced the passive area, decreased the potential of repassivation, and increased the current in the passive area.

The corrosion resistance of 28 metals and 2 metalloids to RFNA was examined, and the effect of alloying iron and nickel with corrosion resistant elements on their electrochemical properties was measured [115].

The corrosion resistance of type 28 steel specimens in RFNA was investigated, with variations depending on the steelmaking method, heat treatment, manganese, and carbon contents and additional alloying [116]. It was shown that intergranular corrosion (IGC) of 128 type steel can be prevented by alloying it with niobium or titanium provided that carbon and manganese content are limited. It was also found that the quenching and tempering of 428 type steel affect its IGC in RFNA, contrary to the known effects on its IGC in other corrosive media.

1.4.1 Corrosion Products in RFNA

Corrosion products in nitric acids can settle as a sludge at the bottom of a tank and become entrained in feed lines to the rocket engine, eventually clogging injector orifices and causing engine failures. The analysis of corrosion products may also give a hint as to which component in a propulsion system is failing due to inadequate compatibility. Aluminum nitrate, a corrosion product often encountered in WFNA or RFNA stored in aluminum tanks, is not very soluble in nitric acid [117]. The effect of iron impurity levels up to 100 ppm as Fe_2O_3 on HDA heat transfer was studied in 30 tests using resistance-heated, circular, Al-6061-T6 tubes [51]. The experimental forced convection heat transfer coefficients were unaffected by iron impurity level.

1.4.2 Protective Coatings for Metals in RFNA

Attempts have been made to develop protective linings of polytetrafluoroethylene (PTFE) and similar materials in RFNA storage tanks, but with limited success. N_2O_4 dissociates to produce NO_2 , which quickly permeates thin layers of polymers and leads to the delamination of the lining from the substrate metal. No coating materials will effectively protect steel or aluminum from RFNA where atmospheric moisture may also have access to the metal [118, 119].

1.4.3 Lubricants for RFNA Service

The only lubricants acceptable for WFNA or RFNA service are chemically inert perfluorinated hydrocarbons or chlorofluorocarbons. Examples of recommended lubricants are Fluorolube, Kel-F oil, Krytox 240AC, or Nordcoseal-147-S. Similar lubricants are used for N_2O_4 service. Conventional hydrocarbon greases and oils must be avoided because they constitute an explosion hazard if mixed with RFNA [120]. One particular lubricant was made from perfluorinated $\text{C}_4\text{-C}_6$ trialkylamines mixed with PTFE powder [121].

1.4.4 Accidental Ignition of Metals in RFNA

Titanium is generally considered to be compatible with either WFNA or RFNA. However, in several instances, exceptionally high rates of attack were observed in RFNA. In these cases, the rate of attack ranged from 10/1000ths to 100/1000ths of an

inch per year and frequently adherent but pyrophoric corrosion deposits formed. The corrosion product was found to be sensitive to heat, shock, and electric sparks, and in two cases it exploded with violence, causing severe injuries and one fatality to attending personnel [122, 123]. The titanium involved in the accident was commercially pure titanium in various stages of metals processing (cold-rolling, annealing, welding). In another incident, several test specimens of a titanium-8% manganese alloy reacted with RFNA, showering a chemist with corrosive liquid.

1.5 Toxicity and Safe Handling of RFNA

1.5.1 Toxicity of RFNA

RFNA contains typically 3 to 16 mass-% NO_2 or N_2O_4 , which substantially increases the vapor pressure of the liquid and readily evaporates as soon as the liquid is exposed to ambient air, creating an inhalation toxicity hazard. The toxicity hazard of accidental inhalation of the red fumes from RFNA is substantially higher than the problems faced when handling WFNA [124]. The occupational hazard with RFNA may actually be higher than that of liquid N_2O_4 because liquid N_2O_4 and mixed oxides of nitrogen (MON) are always handled and transferred in hermetically closed containers under pressure, while RFNA can be poured from one container into another at atmospheric pressure while exposed to the air and thus more likely to be spilled [125–128]. The toxicity of NO_2 escaping from RFNA is essentially the same as that of NO_2 escaping from dinitrogen tetroxide, the other very widely used storable rocket propellant oxidizer. In Volume 1, *Encyclopedia of Oxidizers*, the chapter “Dinitrogen Tetroxide” contains a detailed account of the toxicity of NO_2 .

1.5.2 Protective Equipment for Safe Handling of RFNA

Whereas a gas mask with a filter for acidic fumes may suffice for handling WFNA or MA, handling of RFNA requires a special filter for NO_2 or even a supplied air breathing apparatus to provide adequate respiratory protection of propellant handlers. The red fumes do not provide enough of a visual warning regarding the presence of NO_2 . It is better to rely on special monitoring and warning apparatus.

Serious injury by concentrated nitric acids is not infrequent, accounting for a significant number of cases of disability and death from spills of hazardous chemicals. Toxicologically, the two major forms, WFNA and RFNA, may be regarded as identical, since they are both extremely corrosive and since both emit dangerous fumes. The literature contains reports about fatal RFNA accidents [129, 130].

Protective clothing for propellant handlers in contact with RFNA must be made from RFNA-resistant materials [131]. Several materials for gloves, boots, aprons, and splash shields were evaluated in permeation tests with hydrazine, unsymmetrical dimethylhydrazine (UDMH), and IRFNA [132–134].

1.5.3 Handling, Transportation, Storage, and Disposal of RFNA

1.5.3.1 Safe Handling of RFNA

A 20-page summary on the hazards of handling IRFNA and HDA is provided in Chapter 15 of [135]. The CPIA/M4 Unit 17 (Mar 1976) is 40 pages long and deals with both RFNA and WFNA. It has a materials compatibility list where materials are ranked in four compatibility classes. See also [136].

1.5.3.2 Transportation and Storage of RFNA

The transportation and storage of RFNA would be easier than the storage and transportation of WFNA because no excessive oxygen pressure buildup is expected during storage as long as the NO_2 and H_2O concentrations are kept in the optimum range [137].

1.5.3.3 Disposal of RFNA

At the end of the Cold War, large quantities of RFNA were stored in Russia and the former Soviet republics. As part of the SALT disarmament agreements, the missiles and their support facilities had to be decommissioned and large quantities of this toxic and corrosive material had to be demilitarized. A brief Internet search revealed numerous pieces of information, but they could not be independently verified, and the following survey may not be complete. Numerous international conferences have been devoted to the subject of cleaning up contaminated former military sites so that the areas can be returned to civilian use [138]. Most of the concern at these conferences was about spilled halogenated solvents, transformer oils, and hydrocarbon fuels that have permeated into the ground and aquifers. Some reports list RFNA in one breath with problems in the disposal of plutonium and chemical warfare agents. The problem of RFNA disposal is dwarfed by problems associated with the disposal and accountability of these other chemicals. Some reports discuss RFNA disposal in connection with the disposal of other liquid rocket propellants, such as UDMH (code name: Heptyl), Samin (a mixture of xylydine and triethylamine) or dinitrogen tetroxide (code name: Amyl) [139]. Unfortunately, the storage conditions were not carefully controlled and some of it had already leaked into the ground. The abandoned storage magazines constituted a hazard to the surrounding communities [140]. Various weapon systems used RFNA (“*Melanj*”) and had to be demilitarized [141]. The amounts stored in two military depots at Alyat and Mingechevir in Azerbaijan may have amounted to nearly 2000 metric tons, and similar quantities were found in other locations.

The compositions of RFNA (*Melanj*) were analyzed, and apparently there were different grades, also designated as *azotnaya kislota* (nitric acid), or AK with designations like AK-20k, AK-27p, and AK-27i [142]. *Melanj* AK-20f, AK-20i, and AK-20k contained 17.5–22.5% NO_2 . *Melanj* AK-20f, AK-20k, and AK-27p contained 0.1–1.3% phosphoric acid. *Melanj* AK-20f, AK-20k, and AK-27p were IRFNA and contained 0.3–0.8% anhydrous hydrofluoric acid. One of these mixtures may contain up to 7.5% sulfuric acid in addition to dinitrogen tetroxide and nitric acid. Several methods were evalu-

ated to convert the unwanted rocket propellant oxidizer to commercially useful products, such as fertilizer.

Besides abandoned propellants in Azerbaijan, additional tanks filled with Melanj had to be disposed of in Moldova [143]. Several different methods were evaluated to not only dispose of but also to convert the abandoned and unwanted rocket propellants, including Samin and Melanj, into commercially useful products, such as fertilizer or plastics [144–148]. Ukraine had planned to dispose of all its remaining toxic rocket fuel, most of it known as Melanj, by 2013.

2 Inhibited Red Fuming Acid

Development work during the 1950s revealed that corrosion by $\text{HNO}_3/\text{N}_2\text{O}_4$ mixtures can be greatly reduced by the inclusion of small concentrations of fluoride in the form of hydrogen fluoride. This has usually been achieved by adding liquid hydrogen fluoride (0.7 mass-%) to the oxidizer. The mechanism of passivation appears to be the formation of an impervious coating of insoluble metal fluoride on the surface of the metal. The presence of the fluoride corrosion inhibitor can reduce the rate of attack (in terms of loss of section) on steel and aluminum alloys to acceptable levels, but it also causes a secondary problem due to the formation of significant quantities of low-solubility corrosion products. These corrosion products are troublesome because they do not remain adhered to the walls of the propellant tanks but tend to form semicolloidal suspensions in the liquid or settle as a sludge in the bottom of the oxidizer tank. In either case such material is dangerous since it has the capacity to cause clogging of the propellant feed system, thereby affecting the performance of the rocket engine.

This section on IRFNA includes data on inhibited HDA, which contains more N_2O_4 than IRFNA. The AGENA upper stage propulsion system started operating in 1957. Between 1957 and 1972, several engine modifications and propellant changes were made to increase performance. Notable among the latter was a change from IRFNA to standard HDA (HDA). Hydrogen fluoride was added to both oxidizers as a corrosion inhibitor. Experience showed HF to be less effective in HDA than in IRFNA, and a search was launched for an alternate corrosion inhibitor that would extend the useful life of either of the two oxidizers. Under Contract F04611-72-C-0026 Bell Aerospace Textron developed a superior corrosion inhibitor, phosphorus pentafluoride, which promised long-term storability and extended mission life. The new oxidizer was named modified HDA. Extended storage tests completed under Contract F04611-73-C-0069 showed that the new oxidizer could be stored for 2 years in aluminum and stainless-steel tanks with insignificant corrosion. Under Contract F04611-76-C-0054, the corrosiveness of standard HDA and modified HDA toward a variety of materials in AGENA and integrated secondary propulsion system (ISPS) engines was compared. Modified HDA was found to be significantly less corrosive than standard HDA. Additional data were obtained

concerning the analysis and some of the properties of the two acids. There was no adverse effect on substitution of one corrosion inhibitor for the other. Although HDA is a more energetic propellant than RFNA, experience suggests that it is also more susceptible to problems with corrosion products than IRFNA, and this is one factor that may have restricted the use of HDA.

2.1 Preparation of IRFNA

IRFNA can be prepared from RFNA by the addition of a measured amount of anhydrous hydrogen fluoride ("hydrofluoric acid", HF). In Russia, the following IRFNA compositions were in use:

- AK20 Russian formulation consisting of 80% nitric acid + 20% N_2O_4 (AK = *azotnaya kislota* in Russian = nitric acid)
- AK20F Russian formulation consisting of 80% nitric acid + 20% N_2O_4 + fluorine passivating agent
- AK20I Russian formulation consisting of 80% nitric acid + 20% N_2O_4 + iodine passivating agent
- AK20K Russian formulation consisting of 80% nitric acid + 20% N_2O_4 + unknown additive
- AK27I Russian formulation consisting of 73% nitric acid + 27% N_2O_4 + iodine passivating agent
- AK-27P Russian formulation consisting of 73% nitric acid + 27% N_2O_4 + unknown additive.

2.2 Physical Properties of IRFNA

The physical properties of IRFNA are essentially the same as those of RFNA. The presence or absence of a small percentage (<0.5 mass-%) HF does not make that much of a difference. Some of the physical properties reported in other sections of this book may actually have been for IRFNA instead of plain RFNA.

2.2.1 Freezing Point and Phase Diagrams of IRFNA

The addition of 0.5–0.7 mass-% HF did not significantly alter the freezing point of IRFNA compared to that of RFNA.

2.2.2 Boiling Point of IRFNA

The addition of 0.5–0.7 mass-% HF did not significantly alter the boiling point of IRFNA compared to that of RFNA.

2.2.3 Vapor Pressure and Vapor Phase Composition of IRFNA

Eight modified HDA solutions containing high and low concentrations of 41 and 45% NO_2 , 0.4 and 1.0% H_2O , and 0.5 and 0.7% PF_5 were prepared for vapor pressure measurements in Teflon-lined aluminum vessels [149]. The NO_2 concentration was bumped up 1% above nominal because some NO_2 was lost when admitting the liquid to the evacuated apparatus and filling the vapor space above the liquid. It was necessary to separate the decomposition pressure component of equilibrium pressure from the vapor pressure component, at a fixed temperature. The decomposition pressure arose from the generation of dioxygen gas by the decomposition of nitric acid and the relatively low solubility of oxygen in modified HDA. The vapor pressures for two compositions bracketing the range of compositions studies are graphed in Figure 22.

Figure 22: Vapor pressure of modified HDA in comparison to standard HDA. (Reproduced and modified from [150].)

2.2.4 Density and Partial Molar Volumina of IRFNA

Nine batches of modified HDA containing three levels (42, 44, and 46%) of NO_2 content and three levels of water content (as received, 0.5, and 1.0% H_2O) were prepared to measure the density of HDA containing 0.5% PF_5 instead of 0.7% HF as inhibitor [149]. The composition of the nine acids is given in the legend to Figure 23. No water was deliberately added to the first three blends. The variations in water content reflected minor differences in the starting materials. Calculated amounts of water were added prior to nitrogen dioxide addition during preparation of the other blends to bring the final water content up to 0.5 or 1.0%. Large enough batches were prepared in each

case so that density measurements could be made on portions of the same stock solution. The density was measured in a capillary pycnometer in a thermostatted bath. As shown in Figure 23, all curves have the same slope, allowing extrapolation from one temperature to another within the limits of the graph. Interpolation between curves is less reliable. The curves fall in three families with three different water contents. Density at a given temperature for a given NO₂ content increased with a decrease in water content. Maximum density, at a given temperature and water content, is associated with blends containing 44 mass-% NO₂. The type and amount of inhibitor had only a negligible effect on HDA density (Table 22).

Figure 23: Density of modified HDA as a function of temperature. (Reproduced and modified from [150].)

Table 22: HDA density as a function of corrosion inhibitor

Corrosion inhibitor	Temperature			Density
	°F	°C	K	g/cm ³
None	60.0	15.6	288.7	~1.6492
0.8 mass-% HF	60.0	15.6	288.7	~1.6445
0.4 mass-% HF	60.0	15.6	288.7	~1.6385
0.5 mass-PF ₅	60.0	15.6	288.7	1.6485

2.3 Chemical Properties of IRFNA

2.3.1 Analysis of IRFNA

It is important to maintain the correct amount of HF inhibitor in IRFNA. If the HF concentration is too low, the metals are insufficiently protected. If the HF content is too high, additional corrosion will occur. Various instruments are available that can analyze for HF in IRFNA under field conditions or in the laboratory [151]. One method for determining nitrogen dioxide consists of measuring the nitrogen pressure that develops when fuming nitric acid reacts with sulfamic acid solution. Water is determined by measuring the hydrogen pressure that develops when the water content of an acid sample reacts with calcium hydride. Hydrofluoric acid was estimated colorimetrically through bleaching of the color of an iron salicylate solution. See also [152–154].

In another method, the sample is treated with hydrogen peroxide, neutralized with sodium hydroxide, and then titrated with standardized aluminum chloride solution with a methyl red indicator [155].

One technique for directly measuring fluoride-ion concentrations in IRFNA involves the use of fluoride-selective ion electrodes, where the concentrations are determined by measuring the potential developed between this electrode and a reference electrode [156]. A special procedure involving a buffer solution was devised for weighing the inhibited nitric acid before neutralization, dilution, and measurement. The results were more accurate than those obtainable by the commonly used, and more complex, indirect methods. It works with samples as small as 1 g.

2.3.2 Thermal Stability and Decomposition of IRFNA

2.3.2.1 Storage Stability of IRFNA

The pressure rise in hermetically sealed storage tanks containing inhibited white fuming nitric acid (IWFNA) or IRFNA is basically the same as that observed in WFNA or RFNA without any addition of inhibitor already described in *Encyclopedia of Oxidizers*, chapter “White Fuming Nitric Acid” and Section 1.3.2 above.

Measurements of the pressure rise in sealed aluminum-61S-T6 containers, which had been filled at 294 K (21 °C) leaving only 10% ullage, as a function of the initial com-

position of the acid showed that the equilibrium pressure was achieved after 4 weeks of storage at 327 K (54 °C) [10]. The highest decomposition pressure (7.57 MPa = 75 atm) was observed if the test was started with pure nitric acid containing hardly any H₂O or N₂O₄ (Figure 24).

Figure 24: Maximum decomposition pressure in Al 61S-T6 aluminum drums filled at 294 K with 10% ullage and stored at 327 K (54 °C) for 4 weeks. (Republished and modified from [10], with permission of © 1956 American Institute of Aeronautics & Astronautics; permission conveyed through Copyright Clearance Center Inc.)

All acid samples in the aforementioned experiment contained 0.5% HF as a corrosion inhibitor. If the acid contained 12 to 16% NO₂ and/or 2 to 3.5% H₂O (in addition to 0.5% HF) to start with, the equilibrium decomposition pressure achieved after storage at 327 K (54 °C) for 4 weeks was only on the order of 505 kPa (5 atm). Nitric acid in this

initial near-equilibrium mixture decomposed only to the extent of 0.5%, whereas pure nitric acid decomposed to the extent of 19%, resulting in a mixture of about 9% NO_2 and 1 to 2% H_2O . If the tank was vented during storage, the degree of decomposition progressed even further, because after each venting more HNO_3 decomposed until the new equilibrium was again attained. These decomposition experiments served to select an almost stable and storable RFNA composition containing 2 to 3% H_2O and 13 to 15% NO_2 .

2.4 Compatibility with and Corrosion of Materials in IRFNA

2.4.1 Inhibitors to Prevent Corrosion of Metals in IRFNA

The corrosion of aluminum and other metals in RFNA can be reduced substantially by the addition of hydrogen fluoride. An investigation of the effect of small amounts of hydrogen fluoride in inhibiting corrosion by fuming nitric acid revealed that corrosion rates of 6061-T6 aluminum and Type 347 stainless steel were generally reduced by a factor varying from about 10 to 100, when an initial HF content of approximately 0.75% by mass was used [157]. No further reduction in corrosion rate was obtained by increasing the HF content to 2.0%. A HF concentration of 0.75% was selected as the optimum inhibitor concentration for further tests. The effect on the metals of exposure to the inhibited acids was determined in crevices and in stressed specimens, at weld zones, in galvanic couples, in containers with different ullages and with different sizes of vent holes, with various ratios of metal area to acid volume, with acids containing varying amounts of solid matter, and with acids flowing through orifices and impinging against metal at various velocities. Analytical methods for determining HF content and for determining other constituents of acids were also investigated. Similar methods are described in [158, 159].

The rate of corrosion of welded and unwelded Uniloy 19-9DL and 19-9DX steels and welded CRES-321 by fuming nitric acid in liquid and gas phases at 328 and 344 K (130 and 160 °F) during 35-d tests was measured with and without hydrofluoric acid added as corrosion inhibitor [160, 161]. Because of their ease of fabrication by welding, high strength-to-weight ratio, and relatively good corrosion resistance, these steels were used in guided missiles for the construction of pressure vessels that were to contain fuming nitric acid. Stainless steels 19-9DL and 19-9DX are predominantly austenitic steels containing nominally 19% chromium and 9% nickel with molybdenum, tungsten, and carbon added to increase strength at room and elevated temperatures. Alloys of the general type of 18% chromium and 8% nickel with relatively high carbon content are susceptible to IGC. When the metal had previously undergone IGC by exposure to uninhibited fuming nitric acid, subsequent exposure to HF-inhibited acid resulted not in passivation but extremely severe corrosion. The effect of heat treatment on corrosion, in particular of welded seams,

was of special concern. Only 0.6 mass-% HF in fuming nitric acid already inhibited corrosion.

Measurements were made at 328 K (130 °F) of the extent of corrosion of several metals exposed to the liquid and the gas phase of thermally stable nitric acid containing 11–13% NO₂ and 2–4% H₂O with and without HF added as a corrosion inhibitor [162]. Liquid-phase corrosion of the following metals was readily inhibited by hydrofluoric acid in fuming nitric acid of this composition: aluminum alloys 2S-0 (1100), 14S-T6 (2014-T6), 17S-T4 (2017-T4), 24S-T4 (2024-T4), 61S-T6 (6061-T6), and 75S-T6 (7075-T6); aluminum 2S-0 welded to 356; and chromium-nickel steels 302, 303, 304, 321, and 347, Armco 17-7PH, and Uniloy 19-9DL and 19-9DX. Inhibition of gas-phase corrosion was found to occur readily in the case of the following metals tested: steels 303, 410, 430, and 446 and aluminum 61S-T6, but gas-phase corrosion of steels 4130 and 1020 was usually aggravated by hydrofluoric acid. Exposure of aluminum 61S-T6 and stainless steel 347 to fuming nitric acid with a repeated cycling of temperature between 294 and 344 K (70 and 160 °F) was found not to impair the inhibiting effect of hydrofluoric acid on gas- and liquid-phase corrosion of these metals.

Attempts have been made to explain the mechanism of inhibition by hydrogen fluoride by the fact that the fluorides that form a surface coating on the metals are even less soluble in nitric acids than the corresponding nitrates [163]. Inhibition by hydrogen fluoride is effective in the liquid phase as well as in the vapor phase corrosion of metals exposed to the vapor phase above inhibited WFNA or RFNA. In general, the addition of only 0.1 to 0.5 mass-% HF is sufficient to achieve lasting inhibition and passivation. Only in very rare cases was the inhibitor concentration increased to 0.7%. Such a small amount of additive does not significantly affect the performance of nitric acids as rocket propellants or the ignition delay in hypergolic combinations. The inhibiting effect of HF in RFNA on the liquid-phase corrosion of aluminum alloys and iron alloys was found to be dependent primarily on the formation of a protective layer of a tenacious, insoluble fluoride compound of aluminum or iron, respectively, on the surface of the metal [164].

In acids containing no fluorides the weight loss of aluminum was approximately 1/5 that of stainless steel. Addition of 1% fluoride ion to the acid reduced the weight loss of both metals to practically zero even after 26 d of exposure to the acid at 350 K (170 °F) [165]. The minimum quantity of fluoride ion required to inhibit corrosion was found to be approximately 0.25 and 0.5% for aluminum and stainless steel, respectively, in WFNA and 0.5 and 1% for aluminum and stainless steel, respectively, in RFNA (18% NO₂).

Addition of up to 5% HF to RFNA containing 20% NO₂ will lower the freezing point, reduce corrosion and lower the rate of gas evolution and pressure buildup during storage [166]. The addition of small amounts of HF in either the anhydrous form or 52% HF aqueous solution form to RFNA will lower the freezing point from 216 K (−70 °F) to 194 K (−110 °F). If anhydrous HF is used, a low melting (310 K = −99 °F) eu-

tectic forms with only 0.85% HF in the RFNA. If uninhibited RFNA with 18% NO₂ is stored at 347 K (+165 °F) for two months, the pressure in the drum will rise to 1.31 MPa (190 psig), but an IRFNA with 5 vol-% of a 52% HF solution added will show a pressure rise of only 0.86 MPa (125 psig) after three months.

In an effort to develop a corrosion inhibitor for fuming nitric acids that has corrosion-inhibiting and scale-and-sludge formation properties superior to those of hydrogen fluoride, optimum inhibitor concentrations in Types I and III fuming nitric acids, and inhibitor depletion rates for eight inhibitors including hydrofluoric acid (Table 23) were determined, and effects on the mechanical properties of welded specimens of selected aluminum and stainless steel alloys were measured [167, 168]. Storage tests were conducted for 58 d at 294, 322, and 344 K (70, 120, and 160 °F) with three selected inhibitors. The results showed that ammonium hexafluorophosphate provided better inhibition of the corrosion of 6061-T6 aluminum alloy and 17-7PH and A.I.S.I. Type 304L stainless steels than hydrofluoric acid. Measurements of the mechanical properties of the welded specimens after subjection to the liquid and vapor phases of eight inhibited acid systems for 30 d at 322 K (120 °F) indicated that no significant change in properties was caused by these exposure conditions.

Table 23: Optimum inhibitor concentrations

Compound	Formula	Optimum concentration, mass-%
Hydrofluoric acid	HF	0.7 as HF
Potassium fluoride + HF	1 mol KF ± 2.3 mols HF	0.75 as HF
Ammonium acid fluoride	NH ₄ F•HF	0.5 as HF
Lithium iodate + HF	LiIO ₃ + HF	0.3 LiIO ₃ + 0.6 HF
Potassium periodate + HF	KIO ₄ + HF	0.5 KIO ₄ + 0.6 HF
Trisodium phosphate + HF	Na ₃ PO ₄ + HF	0.4 as H ₃ PO ₄ + 0.6 HF
Orthophosphoric acid + HF	H ₃ PO ₄ + HF	0.4 as H ₃ PO ₄ + 0.60 HF
Ammonium hexafluorophosphate	NH ₄ PF ₆ •NH ₄ F	0.3 as HF

Data source: [167]

Evaluation of the inhibited systems showed that only ammonium hexafluorophosphate provided an inhibited system free of corrosion products and scale in Types I and III acid. Except for a microfilm on the aluminum, the exposed test specimens showed no indication of having been immersed in the acid. The trisodium phosphate and orthophosphoric acid-hydrofluoric acid combinations approximated ammonium hexafluorophosphate. An evaluation of inhibited Types I and III fuming nitric acid systems at optimum inhibitor concentration was performed on welded 6061-T6 aluminum alloy, 17-7PH, and A.I.S.I. Type 304L stainless steels exposed to the liquid and vapor phases for 30 d at 322 ± 0.3 K (120 ± 0.5 °F). The ammonium hexafluorophosphate inhibited-acid systems produced the greatest pressures under both sets of conditions. The hydrofluoric acid produced the least pressure when contained in the stainless-

steel test vessels. The phosphoric acid plus HF system produced the least pressures when contained in aluminum test vessels. All the acid-inhibitor systems provided good inhibition with a minimum of scale and corrosion products at ambient temperature. At 322 K (120 °F), the phosphoric acid and ammonium hexafluorophosphate with 0.6% HF were better than HF by itself. At 344 K (160 °F), the ammonium hexafluorophosphate provided the best inhibition. A spot-check of the concentration of inhibitor remaining in the storage test vessels after 58 d at 322 and 344 K (120 and 160 °F) for both acids showed that ammonium hexafluorophosphate suffered the smallest losses. The HF and the phosphoric acid plus HF inhibitors suffered approximately the same loss ratio in the Type I acid medium at 322 K (120 °F). Zinc salts have been proposed as corrosion inhibitors for nitric acids [169]. Some of the Russian IRFNA modifications contained iodine as a corrosion inhibitor.

Three additives were evaluated as potential replacements for HF in inhibited HDA [170]. The compounds were ammonium hexafluorophosphate, phosphorus pentafluoride and monofluorophosphonic acid. Comparison was based on results from 30-d 305-K (90 °F) static immersion tests with Al-6061 and CRES-347. The inhibitors were tested at three different concentration levels and the metals were exposed separately to acid liquid and vapor. Best results were with ammonium hexafluorophosphate or phosphorus pentafluoride when used in the concentration range 0.4–0.6 mass-%. These two inhibitors performed better than HF in 7-d tests with additional metals at 322 K (120 °F). A major improvement was with stainless steels which were much more compatible with HDA when the replacement inhibitors were used instead of HF.

Several other fluorides and phosphorus compounds such as PF_5 , HPO_2F_2 , and P_4O_{10} have been evaluated as inhibitors in RFNA and WFNA [110–173]. HF is less effective as a corrosion inhibitor in HDA than in RFNA. Phosphorus(V) pentafluoride has been evaluated as an alternate inhibitor for HDA. NMR spectroscopy was used to elucidate the nature of the interaction of PF_5 , HPO_2F_2 and P_4O_{10} with the solvent system 44% N_2O_4 in 100% HNO_3 (HDA) [174]. PF_5 generated the species PF_6^- , HPO_2F_2 , and HF (with some $\text{H}_2\text{PO}_3\text{F}$ present as a minor product). HPO_2F_2 gave rise to $\text{H}_2\text{PO}_3\text{F}$ and HF (with smaller amounts of PF_6 also present).

2.4.2 Corrosion of Steels in IRFNA

Tests were conducted to determine the corrosion behavior of Armco 17-7PH and AISI-1050 stainless steel alloys in RFNA containing various amounts of hydrofluoric acid as an inhibitor [175]. It was found that hydrofluoric acid additions to RFNA markedly reduced the corrosion rate of the alloy. Inhibition was obtained in both liquid and vapor phases at 322 and 344 K (120 and 160 °F), for periods of up to 42 d. It was found that a hydrofluoric acid concentration of 0.25% by weight was marginal for good inhibition, and that a hydrofluoric acid concentration of 0.75% was near optimum. The electrochemical potentials of aluminum and stainless-steel electrodes were observed in

fuming nitric acids with various nitrogen dioxide and water contents, and with added fluoride. It was found that water additions shifted the potential of both aluminum and stainless steel in the anodic direction. Nitrogen dioxide content up to 30% did not produce a significant change in the potential of either electrode. Fluoride additions caused a definite anodic shift in the stainless steel potential and had a tendency to shift the aluminum potential in the cathodic direction.

The corrosion rates of cold reduced and annealed plain carbon steel AISI 1020 tubing in RFNA were obtained by measuring the change in the electrical resistance of the tube with time [176]. Corrosion rates decreased with increasing NO_2 concentration in RFNA in a range of 0 to 14% and decreased with increasing H_2O content in the range from 0 to 3.5 mass-% H_2O . This behavior indicated the possibility that NO_2^+ ion or N_2O_5 were the rate-controlling species in RFNA.

The inhibiting effect of fluoride on the corrosion of AISI-321 (CRES-321) stainless steel by RFNA has been investigated with regard to the influence of the N_2O_4 content of the mixture and the nature of the solid corrosion products formed in such systems [177]. The effectiveness of fluoride inhibition in these mixtures decreased with increasing N_2O_4 content and, for one of these N_2O_4 mixtures (HDA), with increasing water concentration. Investigation of the surface film formed on CRES-321 in the latter mixture has shown it to consist primarily of an oxide layer but some fluoride was also incorporated. The long-term storage of fluoride-inhibited HNO_3 - N_2O_4 mixtures in contact with CRES-321 resulted in the eventual precipitation of an insoluble corrosion product that was later identified as a hydrate of iron(III) fluoride.

2.4.3 Corrosion of Aluminum Alloys in IRFNA

The corrosion of six welded aluminum alloys containers and weight-change specimens immersed in IRFNA for 40, 100, 180, and 360 d at 239, 300, 319, and 339 K (−30, 80, 114, and 150 °F) was measured [178]. The corrosion resistance of tungsten inert gas (TIG)-welded specimens from the base metal/filler metal combinations: Al-3003/1100, 2014/4043, 5052/5052, 1100/1100, 5154/ 5154, and 6061/4043 was determined by the change in weight of specimens suspended in IRFNA and by the effect of the acid on the tensile strength of specimens machined from the walls of the containers at the conclusion of the tests. The corrosion of the welded alloy combinations exposed to IRFNA progressed with time except when exposed at 239 K (−30 °F) where no corrosion occurred at that temperature. The corrosion rates of all the welded combinations, except 5154/5154, were higher at 300 and 319 K than at 339 K. At the highest temperature (339 K), the corrosion rates of the welded combinations, except Al-5154/5154, were retarded due to the formation of protective films. The tensile strengths of the welds and base material were not adversely affected by contact with IRFNA for 1 year at the temperatures investigated. The corrosion rates of the 3003/1100 and 5052/5052 combinations increased, whereas that of the 2014/4043 combination decreased as the water concentration of the IRFNA was increased to 7.5% H_2O . The Al-5052/5052 combination

exhibited the highest corrosion resistance of the three combinations investigated over a range of water concentrations from 3.5 to 7.5% H₂O.

Aluminum alloy Al-2014, which may contain 3.9–5% copper and 0.4–1.2% manganese, suffers intergranular attack in RFNA [179]. The corrosion mechanism was examined by electrochemical impedance spectroscopy.

If an aluminum alloy contains copper, there is a chance that locally galvanic corrosion will occur in an electrolyte like RFNA. The effect of dissolved Cu²⁺ ions and over-and-above-specification levels of water content on the corrosion rate of aluminum alloy Al-2014 (3L65) in IRFNA and the effects of variations in IRFNA composition on the corrosion rates in IRFNA were studied potentiometrically in an electrochemical cell where the potential vs. time was recorded for 200 d [180]. There was an order-of-magnitude increase in corrosion rates after the addition of water. Also, the effects of surface pretreatment (F₂/HF for 24 h) on the surface film composition was analyzed by Auger spectroscopy.

Corrosion rates have been measured for Al-2014 (3L65) aluminum alloy, either untreated or subjected to certain surface pretreatments, in contact with IRFNA, gelled IRFNA (IRFNA + SiO₂ + LiNO₃), and these media containing some added P₂O₅ [181, 182]. The temperature dependence of the corrosion reaction in gelled IRFNA has also been studied electrochemically. The lowest corrosion rates determined by weight change occurred when the alloy had been pretreated with gaseous ClF₃ before immersion in gelled IRFNA or gelled IRFNA containing 0.5 mass-% P₂O₅. This medium gave a low corrosion rate even without ClF₃ pretreatment. Pretreatment with a gaseous HF/F₂ mixture or by electropolishing and anodizing conferred no advantage as judged electrochemically. See also [183].

Addition of gelling agents such as fumed silica to IRFNA does not significantly change corrosion behavior in aluminum alloys [184–189]. The compatibility of gelled IRFNA with aluminum alloys was examined using electrochemical methods, weight loss, and surface observation studies [190]. Comparisons were presented between liquid IRFNA and gelled IRFNA with and without added inhibitor (P₄O₁₀). The Al-1100 and Al-2014 alloys behaved in a similar fashion when exposed to gelled IRFNA, based on weight loss measurements. The addition of phosphoric oxide is beneficial with the Al-1100 systems according to the electrochemical results. However, the weight loss data suggested that the gels were satisfactory even without added P₄O₁₀, especially when compared to a liquid IRFNA system. The XPS data showed that the fluorine from the hydrofluoric acid inhibitor in IRFNA was not consumed entirely by the silica gelling agent and remained available to passivate the metal surface. Aluminum, silicon, and phosphorous will compete for the fluorine present in systems with added HF inhibitor.

2.4.4 Corrosion of Titanium in RFNA

Severe corrosion was observed on two types of chemically pure titanium immersed in RFNA with 8–22% NO_2 . One of the samples held in a stoppered Erlenmeyer flask exploded when the chemist tried to vent eventual overpressure after only a few days of immersion, destroying (triggering similar explosive reactions in) adjacent flasks and spattering acid over the operator and the entire laboratory [122–191].

The powdery corrosion product removed from commercially pure titanium after exposure to 20% NO_2 RFNA was found by XRD and chemical analysis to be titanium metal [192]. Metallographic observations indicated that the possible mechanism of corrosive attack of RFNA on titanium and titanium alloys is through IGC of the all- α or all- β titanium alloys. Similar observations of the mixed α - β alloy indicated a possible galvanic or electrochemical mechanism of the attack by liquid-phase RFNA.

The corrosion of commercially pure titanium in RFNA followed a power law that was not interpretable in terms of any one single mechanism [193]. The effects of stress relief and galvanic action on corrosion rates were determined. The influence of acid composition as well as heat treatment of the metal samples on stress corrosion cracking was further investigated.

Corrosion tests of commercially pure titanium and an 8% manganese alloy in the liquid and vapor phase of anhydrous RFNA (20% NO_2) were conducted at 327 and 344 K (54 and 71 °C) [194]. The exponents in the power laws for the corrosion of the two metals were essentially independent of temperature between 327 and 344 K (54 and 71 °C). Stress corrosion tests of 180° bent and clamped samples of the commercially pure titanium and the 8% manganese alloy in both the stressed and stress-relieved condition at 303 and 344 K (30 and 71 °C) exposed the samples to more serious conditions.

A study showed that the sensitivity of titanium alloys toward ignition with RFNA depended on the presence of a dark coating on the metal surface that was identified as finely divided, powdery titanium metal formed as a corrosion product [195]. Stress corrosion cracking occurred with greater than 6.5% NO_2 and less than 0.7% H_2O in RFNA. Corrosion vs. time relationships of two titanium alloys in anhydrous RFNA (20% NO_2) were determined. See also [196].

2.4.5 Corrosion Products in IRFNA

Three experiments were performed in which CRES-321 stainless steel was exposed to IRFNA at ambient temperature (20–25 °C) [197]. These tests may be outlined as follows:

- (a) a mixture of 56/44 by mass ratio $\text{HNO}_3/\text{N}_2\text{O}_4$ (i.e., HDA) stored in a small steel tank for a period of 150 d;
- (b) a mixture of 70/30 by mass ratio $\text{HNO}_3/\text{N}_2\text{O}_4$ stored in a thick-walled PTFE vessel with two stainless-steel specimens (bar, 18 mm diameter, 14 mm long) for a period of 300 d; and

- (c) 100% HNO_3 , stored in a PTFE vessel with steel specimens as in item (b) above, for a period of 220 d.

The tests were terminated when visual inspection of samples of the liquid revealed the presence of particulate matter in suspension. Attempts were then made to isolate the solid product by expelling the liquid from the test vessel and passing it through a PTFE filter (pore size 100 μm). These results clearly indicated the corrosion product to be a form of iron(III) fluoride, but although both the IR and XRD data showed that the material was hydrated, most likely $\text{FeF}_3 \cdot 3\text{H}_2\text{O}$, the only form of iron (III) fluoride known to be green, is the anhydrous form. The corrosion of 18/8 stainless steel by the nitric acid-based propellants IRFNA and IHDA resulted in the formation of a solid reaction product, which may be formulated as $\text{FeF}_3 \cdot x\text{H}_2\text{O}$ ($0 < x < 1$). This compound is very hygroscopic and rapidly converts to $\text{FeF}_3 \cdot 3\text{H}_2\text{O}$ if exposed to atmospheric moisture.

2.4.6 Test Methods for the Study of Corrosion of Metals in IRFNA

Electrochemical studies demonstrated that the electrode reaction

occurred on the surface of a rhodium electrode [198]. Platinum could also be used as a reference electrode, although its performance was slightly inferior to that of rhodium. Electrochemical studies indicated that stainless steels corrode in $\text{HNO}_3/\text{N}_2\text{O}_4$ mixtures by a mechanism involving transpassive layer breakdown. This breakdown can be prevented by cathodic polarization or by the addition of hydrogen fluoride or phosphorus pentafluoride. The results were consistent with fluoride functioning as an anodic film-forming inhibitor. Sulfuric acid can also function as an inhibitor, but its performance was less satisfactory than that of fluoride.

The solubility of corrosion products in modified HDA was found to be relatively independent of temperature and initial nitrogen dioxide or water content, but highly dependent on the specific species present in the acids, from competing corrosion reactions [149]. Metal couples typical of those in propellant containment devices were exposed to modified HDA to obtain further corrosion product solubility data and to test for passivation of the metals with time. No passivation was noted within 1 month. Corrosion took place at a relatively constant rate.

2.4.7 Tank Storage Tests with IRFNA

Tanks that had held IRFNA and were stored in a controlled storage environment at 303 K (85 °F) and 85% relative humidity for 4–6 years were emptied, cleaned, and dissected for metallurgical analysis [199]. The corrosion effects of the stored propellants on the internal metal surfaces were negligible, with no serious degradation of strength or structural integrity occurring. Corrosion occurred primarily due to pitting, gas- and

liquid-phase interactions occurring during storage, manufacturing defects, and at the manifold tubing welds.

Thousands of Bullpup missiles using Type III-A IRFNA per MIL-N-7254C as the oxidizer was fielded during the 1960s, and several were examined for corrosion after they were decommissioned and unloaded after 10–12 years in the field. No leakage of the missile tanks had occurred during the 10-year storage period [200]. Analysis of the residues removed from the oxidizer tank indicated only slight metal attack and dissolution. The degree of corrosion that did occur was considered insignificant and would not have affected the functional capability of the missile system. Some slight corrosion of stainless-steel components present in the oxidizer tank was noted but should present no serious problems.

2.4.8 Other Compatibility Problems in IRFNA

Ignition of titanium in RFNA has been the cause of severe accidents [122].

One of the main applications of IRFNA in the upper stages of launch vehicles was in AGENA [150]. Numerous material compatibility studies were performed in support of that upper stage program.

A spontaneous explosion of a missile tank of a target drone containing IRFNA was reported some time ago in a tropical, hot-climate country such as the Philippines. Preliminary results from failure analysis indicated that the major cause for the explosion was probably due to the overpressure from the oxidizer tank containing the IRFNA. It was concluded that the burst tank was negligently overfilled when originally loaded with IRFNA. Based on these findings, the shelf life of the units filled with the acid was reduced to no more than 2 years. Because a 2-year limit had operational and logistical implications, it was then proposed to quantify the rate of reaction of oxidizer with tank metals by taking microcalorimeter measurements and extrapolate to a safe shelf life from there [201]. The reaction of nitric acid with metals is exothermic and can be detected by a microcalorimeter.

2.4.9 Filter Screens for IRFNA Service

The inlets to propellant valves are usually protected by filters to retain particles that might get lodged on the valve seat and cause the valve to leak when it is commanded shut. The screen material on the filters must be compatible with the propellant, which in the case of IRFNA or NTO is a difficult task. The nitrate film growing on the thin metal wires might cause a narrowing of the passages and increase the pressure drop or embrittle the wires. Similar wire mesh is used in surface tension propellant management devices in propellant tanks for 0-g operation. The long-term effects of propellant immersion on fine micronic stainless-steel wire cloth were studied for IRFNA and nine other propellants [202]. Immersion time histories reported in the literature ranged from 3 months to 7 years.

2.5 Toxicity and Safe Handling of IRFNA

The toxicity and precautions for the safe handling of IRFNA are essentially the same as those for RFNA. The addition of hydrofluoric acid would aggravate any skin injuries if IRFNA instead of RFNA is accidentally spilled on skin.

2.6 Disposal of IRFNA

Disposal and demilitarization of IRFNA is complicated by the presence of corrosion inhibitors such as HF and H_3PO_4 . In addition, some of the Russian IRFNA modifications that needed to be demilitarized after the SALT agreements contained some iodine. Disposal and spill cleanup of IRFNA has been practiced for many decades, and there exists a good database on available methods for safe handling of this oxidizer, for instance Chapter 4 in [203].

Techniques used for demilitarization of IRFNA would vary depending on whether it is disposed of simply to get rid of it at any cost whether more economical disposal methods are needed, where some of the nitric acid is recovered in sufficient purity that it can be used for other commercial purposes, such as nitration reactions of organic compounds for WFNA or fertilizer for concentrated or dilute HNO_3 .

In the US, demilitarization of decommissioned LANCE intermediate-range ballistic missiles posed a problem in the disposal of IRFNA and UDMH propellants off-loaded from these missiles [204]. Some of the decommissioned LANCE missiles were later used as practice targets for antiballistic missile interceptor field tests.

One method for the recovery of useful products such as 100% HNO_3 involve first filtering the IRFNA to remove particulate contamination, then distilling or sparging out the NO_2 , and then distilling the HNO_3 after adding additional H_3PO_4 in an amount at least five to six times that of HF [205]. The same equipment can also be used to regenerate contaminated, aged RFNA or to convert IFRNA to RFNA if these oxidizers are returned from the field after long storage times and after they no longer meet the MIL-SPEC requirements.

3 Gelled Nitric Acids

Gelled propellants are non-Newtonian fluids and therefore exhibit a non-linear relationship between the stress and deformation rate. Depending on the gelling agent used, gelled propellants may also have a finite yield stress. Stresses applied to the fluid below the yield stress will not cause the fluid to flow, but they deform like a solid. Numerous rheological models exist for non-Newtonian fluid mechanics, and the choice of rheological model for a particular fluid depends on how well they match experimental data.

One of the potential benefits of gelled liquid fuels is that gelled liquid fuel propulsion systems in missiles can meet insensitive munitions (IM-LOVA) safety criteria, while many of the solid propellant missiles currently in service cannot. Extensive safety testing, in particular cook-off behavior, has been done with gelled propellant propulsion systems.

Like efforts with other rocket propellants, nitric acids have been gelled as a method to prevent or slow down leakage during storage or sloshing in a rapidly moving missile. Most of the gelling effort has been devoted to RFNA and IRFNA, but few investigators have attempted to produce WFNA gels. In either case, the selection of gelling agents for nitric acids is limited by the reactivity of most organic gelling agents with nitric acid. Organic gelling agents like those used for gelling fuels would rapidly be destroyed in fuming nitric acids. That leaves mostly inorganic gelling agents, which have the necessary chemical resistance but will not improve the rocket performance properties of WFNA or RFNA. Inorganic gelling agents like fumed silica will add inert ballast to propellants, will form troublesome residues in places where they interfere with the operation of the rocket engine, and may settle out during long-term storage. Despite half a century of research and development of gelled hypergolic bipropellants, substantial amounts of money invested in demonstration programs, these gelled propellants have not found any practical application and have not yet flown in a fielded, mass-produced missile.

3.1 Gelled RFNA

NO₂ from spilled gelled RFNA would evaporate more slowly and constitute less of a hazard than spilled ungelled RFNA. The main gelling agent tested for RFNA is fumed silica, also known under the brand names of Cab-O-Sil and Aerosil [206]. The compatibility of gelled IRFNA with aluminum alloys is not much different from that of ungelled IRFNA [189]. The fumed silica that is used as the gelling agent absorbs and removes part of the HF inhibitor, but enough HF remains in solution to passivate the metal surfaces. Another gelling agent is finely divided lithium nitrate [207]. RFNA has been gelled using 4.25 mass-% sodium silicate [208].

The rheological properties of gels prepared from water, RFNA, and UDMH with aerogel silica were investigated over a wide range of gelling agent concentrations [209].

Fumed silica is hygroscopic, and it absorbs water readily from the surrounding environment. The amount of moisture absorption on the fumed silica surface correlates directly with the ambient humidity and can reach 12% by weight at an atmospheric relative humidity of 90%. The silica intended for gelling propellants must be dried in a vacuum drying oven at 383 K (110 °C) and a pressure of <138 mbar for at least 4 h prior to use to ensure the silica has minimal water content.

RFNA gels are usually produced using fumed silica as the gelling agent with concentrations from 3 to 5% by mass. Measurements of the viscosity of 3 to 5 mass-% silica/IRFNA gels were plotted over a range of viscosity measurements on a common plot, although no distinctions were made between different gellant concentrations and the viscosity variation for a single gellant concentration [210]. Thixotropy and yield stress measurements were performed to further classify the behavior of the gel propellants. IRFNA and hydrogen peroxide oxidizers, gelled with silica, were characterized as yield thixotropic fluids with significant shear yield stress. Creep tests were conducted on two rheological types of gels with different gellant contents, and the results were fitted by a viscoelastic constitutive model. The effect of temperature on the rheological properties of gel propellant simulants was also investigated. A general rheological classification of gel propellants and simulants was proposed. The hydroxypropylcellulose/methylhydrazine (MMH) gels were classified as shear-thinning, time-independent fluids with low yield stress values.

RFNA gels were mixed containing 3, 4, and 5% fumed silica by mass [211]. The variation of rheological properties for different silica concentrations and effect of age on the gel rheological properties were measured and compared to model predictions. The RFNA gels were thixotropic, leading to large variations in viscosity and yield stress measurements. Pre-shearing the samples allowed for more repeatable results that should be more representative of the fluid conditions entering a rocket injector. Other factors, e.g., thixotropy, influencing the rheological properties were considered. A series of aging tests were performed to determine whether the rheological properties of the RFNA/SiO₂ gels changed with time. Two 4% silica/RFNA gels were made, and the shear-thinning behavior and yield stress of these gels was measured the day of the mix, 4 d after the mix, 9 d after the mix, and 14 d after the mix. No discernible trend was observed for the yield stress or consistency index for both 4% gel mixes, but the 4% silica/RFNA gels showed a decrease in the power law (PL) index over the 2-week measurement period. The increased shear-thinning behavior suggested that the silica-silica hydrogen bonds were being weakened over time.

Despite the availability of viscosity data, knowledge of the viscosity of a gel like IRFNA gel is not sufficient to predict the pressure drop across an injector in a rocket engine. The discharge coefficient is assumed, and hardware must be fabricated and tested to verify the validity of the assumed discharge coefficient. The propellant formulator does not know the impact on the injector design when the viscosity profiles of gel fuels and oxidizers are altered. Without information about the impact of viscosity on the injector design one cannot distinguish between hardware design problems and propellant formulation problems.

Fumed silica with a mean particle size of 12 nm was evaluated as a gelling agent for IRFNA [212]. A mixing time of 30 min was sufficient for preparing the gel. Operating at different temperatures, gelling was possible in a temperature range of 269 to 308 K (−4 and 35 °C), but 298–308 K (25–35 °C) was more appropriate. The gel with 3–4% SiO₂ needed to age 24 h. During this period the gel viscosity increased up to

30% compared to the viscosity of the gel immediately after its preparation. The gel had good stability in a temperature range of 221 to 337 K (−52 to +64 °C). The prepared gel retained its desirable rheological properties for at least 6 months. Mechanical stability test under acceleration of 500 g for 30 min showed that the prepared gel had suitable mechanical stability. The gel had desirable rheological properties, such as shear thinning, thixotropic behavior, and hysteresis.

White Fuming Nitric Acid

Nitric Acids

Although chemically speaking there is only one nitric acid with the formula HNO_3 , we have subdivided the chapter on nitric acids into three subchapters in *Encyclopedia of Oxidizers*, dealing with four technical grades of nitric acids of different chemical composition: **White Fuming Nitric Acid** (WFNA), **Red Fuming Nitric Acid** (RFNA), and **Mixed Acid** (MA). There are two variants of RFNA, one called **Inhibited Red Fuming Nitric Acid** (IRFNA) and another called **High Density Acid** (HDA), both of which are included in the RFNA chapter.

1 White Fuming Nitric Acid

Pure nitric acid, HNO_3 , CAS RN [7697-37-2] in the freshly prepared state is a colorless liquid which forms white fumes in moist air and solidifies at 231.5 K (−41.6 °C) forming colorless crystals. In practice, it does not stay colorless very long, because a slow, un-stoppable decomposition leads to its visible contamination by a decomposition product, nitrogen dioxide, which stains it yellow. For several reasons, pure nitric acid is hardly ever used as rocket propellant. In most cases, physical and chemical properties of the pure compound are only determined in laboratory experiments for academic reasons and to use it as a standard reference substance in the analysis for other grades of nitric acid containing additives or contaminants. Additives serve the purpose of reducing the rate of decomposition and reducing the rate of corrosion of metals in the acid. Contaminants come from the acid decomposition itself, are absorbed from the atmosphere if the acid is exposed to air during transfer, or are leached from container materials.

1.1 Nomenclature

The English language literature often abbreviates **White Fuming Nitric Acid** as WFNA. For practical applications, WFNA is not really 100% HNO_3 , but depending on its age, it will contain up to 2% H_2O and up to 0.5% NO_2 , which causes the yellow discoloration of the liquid. Already a small percentage of NO_2 suffices to color the liquid yellow.

Nitric acid containing more than 10% NO_2 is generally called **Red Fuming Nitric Acid**, abbreviated RFNA, and will be described in a separate chapter in this volume devoted exclusively to this rocket propellant oxidizer.

If RFNA contains a small percentage of hydrofluoric acid (hydrogen fluoride) as a corrosion inhibitor, it is called **Inhibited Red Fuming Nitric Acid**, abbreviated as IRFNA.

In the distant past, NASA and other government agencies in the United States commonly used abbreviations which designated the nominal composition of nitric acid oxidizers. For WFNA, the digit following the abbreviation designated the water content, e.g. WFNA-7 contained 7 mass-% H_2O . For RFNA, the first of the two numbers following the abbreviation designated the water content and the second and third digit designated the NO_2 content. For instance, RFNA-3-14 would have been an oxidizer containing 3 mass-% H_2O and 14 mass-% NO_2 .

1.2 History of Nitric Acid Usage as a Rocket Propellant

Nitric acid was first used as a rocket propellant in various German missiles during World War II. The German code names were *S-Stoff* for 90% nitric acid/10% sulfuric acid or nitric acid/ferric chloride and *SV-Stoff* or *Salbei* for 85% nitric acid/15% sulfuric acid or nitric acid/dinitrogen tetroxide. Some versions of *Salbei* contained iron(III) nitrate or iron(III) chloride as ignition catalysts. In the US arms inventory, small missiles using nitric acid oxidizer were the BULLPUP air-to-ground missile, surface-to-air anti-aircraft missiles were several generations of NIKE, starting with NIKE-AJAX, and a tactical IRBM missile was the LANCE. All these are now only of historical interest, and there are no missiles active on the US side that still use nitric acid as the oxidizer. Launch vehicles using nitric acid were the highly successful AGENA which has flown as a second stage on numerous first stage launch vehicles (THOR, ATLAS, DELTA, TITAN). Third world countries continue to use nitric acid as a storable rocket propellant. Nitric acid/unsymmetrical dimethylhydrazine (UDMH) propellant combinations have flown in second stages of Russian launch vehicles, such as the S-3 stage with more than 400 flights. SCUD was the first tactical ballistic missile developed by Russia using storable propellants. SCUDs have gone through several development and improvement changes in Russia and were copied by several third world countries. Several SCUDs were flown by the US Army and used as targets for development of anti-missile rockets in the ballistic missile defense program. Later some decommissioned LANCE missiles were used as targets because the plume signature was similar to that of SCUDs. Although WFNA is not currently used as a rocket propellant, we are summarizing its properties here because it may be used for making RFNA or IRFNA or nitrate ester rocket propellants and plasticizers. Sometimes WFNA is used for laboratory ignition delay tests with candidate hypergolic fuels.

2 Production of White Fuming Nitric Acid

Nitric acid is an important bulk chemical product of the chemical industry, mostly the fertilizer industry. It is an important intermediate in the synthesis of many other chemicals. Nitric acid is produced by catalytic oxidation of ammonia with air or oxygen over a gauze of platinum or platinum/rhodium wire mesh

If ammonia and oxygen (air) were allowed to react under equilibrium conditions, nitrogen and water would be the only products, worthless products. There are various variations of this three-step process, which differ mostly in the operating pressure. For instance, the Berlin-Anhaltische Maschinenbau A.G. (BAMAG) combination process operated at 1, 4, and 8 atm pressure for steps 1, 2, and 3. Because reaction step 1 is a highly exothermic combustion process, the catalyst loss may amount to 44 mg of platinum per ton of nitric acid produced. Quite often, the intermediate nitrogen dioxide/dinitrogen tetroxide is not produced in industrial plants devoted exclusively to the production of this rocket propellant oxidizer but is diverted from an existing nitric acid production stream and later purified to meet rocket propellant specification purity criteria.

An unwanted by-product of this process is nitrous oxide, N_2O , which until recently was just vented to the atmosphere since there were only few other uses for it. Typical nitric acid plants produce 2–9 kg N_2O per metric ton of HNO_3 produced. Only after N_2O was recognized as a “greenhouse gas” contributing substantially to global warming, has the industry taken steps to minimize emissions of this by-product [1, 2]. Recently, within the last 20 years, the interest of rocket propellant chemists has been expanded to include nitrous oxide, and the rocket people would dearly like to see the N_2O captured and made available to rocket propulsion companies at a reduced price. Government-imposed N_2O -emission restrictions are likely to increase the price of nitric acid in the future [3].

The most common form of nitric acid in commercial trade is weak nitric acid, which is the azeotrope which contains only 69.2 mass-% HNO_3 and boils at 394.9K (121.8 °C). Most nitric acid production facilities take the product concentration only to this level, leaving 30% water in the product. Weak nitric acid is of insufficient strength to be used as an oxidizer in rocket propellants. Weak nitric acid is still called “concentrated nitric acid” in many publications.

Anhydrous WFNA is prepared from concentrated nitric acid in a subsequent process by distillation from a dehydrating chemical (concentrated or fuming sulfuric acid, phosphorus pentoxide, magnesium nitrate) or by a high-pressure $\text{NO}_2 + \text{O}_2$ reaction

method developed by the German chemical company Pintsch Bamag in Berlin. That process and a similar process by DuPont essentially takes RFNA and heats it with additional dioxygen at higher temperature and pressure, then removes the excess $\text{NO}_2/\text{N}_2\text{O}_4$.

99% nitric acid can be obtained from a 71% aqueous solution of nitric acid by electrolysis in the anode section of a diaphragm cell [4]. The net result of electrolysis is the decomposition of some of the water and a consequent increase in the concentration of the nitric acid.

2.1 Production Statistics of Nitric Acid

The industrial base of the chemical industry in any country is based on its ability to produce ammonia and, as the next step by combustion of ammonia, nitric acid, and ammonium nitrate. Both are important fertilizers for the agricultural industry to feed a growing domestic and world population and to produce food exports if the soil and weather conditions permit. The only known strong nitric acid plant in the US (LSB Industries Inc., El Dorado, AR, USA) uses the direct strong nitric (DSN) acid Uhde process. The amount of nitric acid and dinitrogen tetroxide (NTO) diverted during HNO_3 production used as a rocket propellant is an insignificant fraction of the total HNO_3 production in any country. Even if we include the fraction used for production of nitrocellulose and double-base propellants, the amount is still very small. Another small fraction is or was used to produce the traditional dynamite made by soaking glycerol trinitrate in kieselguhr. In the USA about 65% of the nitric acid produced is consumed in the manufacture of fertilizers, for example, ammonium nitrate. In 2007, 76% of total US nitric acid production was converted at the production site to ammonium nitrate. We are listing here only production capacity numbers to give the reader a perspective

Table 1: World output of nitric acid.

	1962–1963	1965–1966
Millions of metric tons, based on 100% HNO_3		
USA	3.4	4.7
USSR	2.5	3.7
West Germany	2.2	2.55
France	1.73	2.2
Italy	1.05	1.3
Norway	1.0	1.25
Netherlands	0.7	0.95
United Kingdom	0.6	0.90
Rest of the world	5.12	5.85
Total	18.30	23.40

Data source: [5]

Table 2: Historical and projected US nitric acid production.

Year	Nitric acid produced, thousand metric tons
Actual	
2006	6447
2007	6866
2008	7072
2009	7284
2010	7502
2011	7000
2012	6790
2013	6730
2014	6460
2015	6650
2016	6780
2017	7050
2018	7130
2019	7200

Data source: [6]

of the ease of diversion of such chemicals for rocket propellant and explosives manufacturing. Nitric acid is used in the manufacturing of nitrocellulose and nitrate esters for double-base propellants. Table 1 and 2 give nitric acid production statistics for the World and for the USA.

Approximately 3/4 of US nitric acid production is consumed in making ammonium nitrate, while adipic acid manufacture (for Nylon and other polyamides) consumes about 9%.

2.2 Purification of Nitric Acid

Many of the physical properties reported for nitric acid are of dubious value because the investigators may not have used truly pure nitric acid. In many cases, the nitric acid already decomposed while the measurement was in progress.

Attempts to prepare pure nitric acid by fractional crystallization of 98.5% nitric acid were partially successful [7]. The highest concentration attained by this method was 99.67–99.79% HNO_3 . The product was a white crystalline solid which formed a straw-colored liquid when melted. This led the investigators to believe that pure nitric acid is stable only below its freezing point. Actually, pure nitric acid can be kept at 273 K (0 °C) for many hours without visible signs of decomposition.

Aged nitric acid that has turned yellow by partial decomposition can be purified by bubbling ozonized oxygen (5% O_3 in O_2) through the solution [8]. After bubbling

ozonized oxygen through the acid for about 5 minutes, the yellow color disappeared and the acid was a clear colorless liquid like water.

3 Physical Properties of White Fuming Nitric Acid

Published physical properties for nitric acid HNO_3 vary widely, depending on the purity of the sample used for the physical property determination. In particular, older data are often plagued by inaccuracies due to the lack of purity of the acid used. The problem arises from the fact that pure nitric acid is not stable and will slowly decompose (See Section 4.4, Decomposition of Nitric Acid), even while the measurements of physical properties, in particular measurements at elevated temperatures, are in progress. Sometimes the acid needs to be analyzed once at the start of the physical property measurement and again after the measurement has been completed.

Although pure nitric acid is not used as a rocket propellant, we have assembled here a fairly complete summary of its physical properties because it would be even more difficult to determine these properties for mixtures of WFNA with other oxidizers, such as RFNA or IRFNA. In many cases the properties of HNO_3 -containing mixtures must be interpolated or extrapolated from other data, starting with WFNA. For rocket applications, most of the nitric acid goes into nitrating organic compounds, such as cellulose, glycerol or ethylene glycol. In designing process equipment for the production of these solid propellant ingredients, the physical properties of nitrating acid must be known. Spent nitrating acid from industrial nitrating processes is often reprocessed to recycle the nitric acid and use it for other purposes. The design of equipment for the recovery of nitric acid from spent acid will depend on a complete knowledge of the properties of pure nitric acid.

When referencing sources of physical data, one must always specify if the data were obtained with freshly prepared, chemically pure nitric acid or if they were obtained with a technical grade of “white fuming nitric acid”. Because pure nitric acid must be freshly prepared immediately prior to the measurement, only few experimenters have gone through the extra trouble of using freshly prepared, chemically pure nitric acid. Even if the freshly prepared acid was stored in the frozen state to preserve it, it may still have some impurities that evolved when it was thawed. The data for the pure nitric acid are only of academic interest, because acid this pure would rarely be used as a rocket propellant. The data for the technical grade WFNA are of more practical importance. Both are summarized in this chapter of this book.

Summaries of physical and chemical properties of WFNA nitric acid are found in the following publications: [9–14]. The summary published by Stern, Mullhaupt, and Kay in *Chemical Reviews* in 1960 is a very thorough compilation of good data. We wished summaries like that were available for all chemicals in this book.

The molecular mass of nitric acid is 63.0128 g/mol equivalent to 15.8698 mols/kg [15].

3.1 Freezing Point and Phase Diagrams of WFNA Mixtures

Literature data on freezing point of pure nitric acid are summarized in Table 3. The data from various sources are fairly consistent.

Table 3: Literature data on freezing point of pure nitric acid.

Freezing point		Authors	Year	References
K	°C			
230.6–232.1	–41.0 to –42.5	Biltz and Huelsmann	1932	[16]

231	–42	Weast	1984	[25]

The freezing point diagram of the binary system $\text{HNO}_3/\text{H}_2\text{O}$ in Figure 1 shows two distinct maxima which can be attributed to the formation of stoichiometric hydrates of nitric acid, ($\text{HNO}_3 \cdot \text{H}_2\text{O}$ and $\text{HNO}_3 \cdot 3\text{H}_2\text{O}$) [18]. For the application of WFNA as a rocket propellant we are only interested in nitric acid containing less than 10% H_2O . The freezing point diagram illustrates the fact that the freezing point cannot be taken as an indication of acid concentration. For instance, an acid sample freezing at 228 K (–45°C) might contain 85 or 94 mass-% HNO_3 .

Figure 2 is a more detailed representation of the high-concentration end of the diagram in Figure 1. The NACA report has a much nicer, more detailed diagram of this system covering the entire range of compositions [26].

Table 4 contains measured raw data for the freezing point of WFNA with up to 20 mass-% water.

Even a small percentage of water causes the freezing point of WFNA to go down noticeably (Table 5).

Figure 1: Freezing point diagram in the system HNO₃/H₂O. (Reproduced and modified from [18].)

Table 4: Freezing point of technical grade nitric acid.

Mass fraction		Freezing point	
HNO ₃	H ₂ O	K	°C
1.000	0.000	231.85	-41.3
0.956	0.044	230.85	-42.3
0.953	0.047	230.35	-42.8
0.907	0.093	228.75	-44.4
0.808	0.192	219.85	-53.3
0.800	0.200	218.15	-55.0

These data were extracted from [18]; See also Figure 1.

99.74	0.26	231.2	-41.9	-43.4
99.65	0.35	231	-42.1	-43.8

Data source: secondhand data from [28, p. 157]

Nitric acid hydrate crystals have been observed in polar stratospheric clouds in polluted atmospheres. Therefore, the HNO₃/H₂O binary liquid/solid phase diagram in the region of nitric acid trihydrate and nitric acid dihydrate was investigated using highly sensitive DSC and IR spectroscopy of thin films [29]. There are several eutectic transitions in the region of nitric acid trihydrate, dihydrate, and monohydrate. A new solid phase was found that undergoes a transition at ~228 K for samples in the range 54–75 mass-% HNO₃. Phase diagrams of more dilute nitric acids in the mole fraction

range below $\chi \text{HNO}_3 = 0.25$ are of interest mostly for atmospheric chemistry and not so much as rocket propellants [30]. Various phases, including a possible pentahydrate, were examined by XRD and IR spectroscopy.

3.2 Boiling point of WFNA

The thermal instability of nitric acid makes an accurate determination of its normal boiling point very difficult. For this reason, the accuracy of experimentally determined values of the boiling point is often questionable. Literature data on boiling point of pure nitric acid are summarized in Table 6.

Table 6: Literature data on boiling point of pure nitric acid.

3.3 Vapor Pressure and Vapor Phase Composition of WFNA

3.3.1 Vapor Pressure of WFNA

The vapor pressure of nitric acid at room temperature is sufficiently high, 50 mmHg at 293 K (20 °C), to release noxious fumes which make the handling of this oxidizer a hazardous operation. In moist air the vapors will form a white mist which is an acute inhalation hazard. In addition to splash protection, respiratory protection is required when transferring WFNA from one container to another container by pouring it in open air.

It is difficult to measure vapor pressure of WFNA at temperatures above room temperature because the acid will start to decompose.

Vapor pressure measurements of pure nitric acid in the narrow temperature range between 263 and 293 K are shown in Figure 3 and can be expressed by the equation

$$\log_{10} P = 8.986 - \frac{2141}{T}$$

where P is the pressure in mmHg and T is the temperature in kelvin [34, 35].

Figure 3: Vapor pressure of pure nitric acid. (reproduced and modified from [36].)

Legend: + Experimental points, • Extrapolated from isotherms, -- Interpolated, - - - Least squares fit

The vapor pressure of pure nitric acid can be calculated from the equation

$$\log p_v = 7.61628 - 1486.238/(t + 230)$$

where p_v is the vapor pressure in mmHg and t is the temperature in °C. The vapor pressure calculated from thermodynamic data agreed well with experimental data in Table 7. See also [31].

Droplet evaporation experiments were performed with single drops of WFNA and of aniline on a hot surface in the temperature range 573–1373 K (300–1100 °C) [37]. These drops showed initial evaporation periods, during which the diameter of the drops did not diminish. The influence of bubble-inflation on the course of the evaporation, and on the total time of evaporation for a given initial diameter was studied. The evaporation times were exponential functions of the temperature of the hot surface. It was demonstrated that, for a constant temperature, the evaporation times per 1 mg of drops can be longer or shorter for nitric acid than for aniline depending on the actual value of the temperature.

Table 7: Vapor pressure of pure nitric acid.

Temperature		Vapor pressure	
K	°C	mmHg	kPa
273.15	0	14.4	1.919
277.6	4.44	19.0	2.533

3.3.2 Vapor Phase Composition of WFNA Mixtures

The vapor phase composition as a function of liquid phase composition and temperature must be known if one wants to concentrate dilute nitric acid by distillation. Nitric acid and water do form an azeotrope, which is why WFNA (100% HNO_3) cannot be made by simple distillation of 68% HNO_3 .

The azeotrope formation in the HNO_3/H_2 system is evident from the vapor pressure curves as a function of acid composition, which show a minimum near 35 mol-% HNO_3 (depending on the temperature) (Figure 4).

Measured values of the partial pressures of H_2O and HNO_3 above nitric acid solutions with 50–100 mass-% HNO_3 at 273 and 293 K (0 and 20 °C) were used to calculate the heat of evaporation of nitric acid [38].

Very concentrated solutions of HNO_3 contain free molecules of HNO_3 , H_2O , and the ions NO_3^- and H_3O^+ , and a hydrate ($\text{H}_2\text{O} \cdot \text{NO}_2\text{OH}$) which has no vapor pressure. Calculations involving the partial vapor pressures of pure HNO_3 and H_2O and the coefficient of ionization, which was determined spectrographically, confirmed the existence of a monohydrate between 75 and 100 mass-% HNO_3 [39]. The rate of evaporation of nitric acid droplets is an important design criterion for injectors in rocket engines, see [37]. See also [40, 41].

Figure 4: Vapor pressure isotherms in the HNO₃/H₂O system. (reproduced and modified from [36].)

3.4 Density and Partial Molar Volume of Nitric Acid

3.4.1 Density of Pure Liquid Nitric Acid

Density data for liquid nitric acid are summarized in Table 8.

Table 8: Single-point density data for pure nitric acid from the literature.

Temperature		Density	Authors	Year	References
K	°C	g/cm ³			
283	10	1.5310	Intl. Critical Tables, Vol. 3, p. 59	1928	[42]
273	0	1.5492	Mason, Petker, and Vango	1955	[43]
298	25	1.5037	Mason, Petker, and Vango	1955	[43]
283	10	1.5310	Antipenko, Beletskaya, and Krylova	1958	[21]
273	0	1.5492	Fine	1962a	[44]
298	25	1.5027	Weast, CRC Handbook Chem. Phys. 64 th Ed.	1984	[25]

The density of the pure nitric acid as a function of temperature can be calculated by the equation [44, 45]:

$$\rho = 1.5492 - 0.00183t$$

where ρ is the density in g/cm^3 and t is temperature in $^{\circ}\text{C}$. Densities calculated from this equation have been tabulated in Table 9 for convenience.

Table 9: Temperature dependence of density of anhydrous nitric acid.

Temperature		Density	Remarks
$^{\circ}\text{C}$	K	g/cm^3	
0	273	1.5492	Freezing point of water
5	278	1.5401	
10	283	1.5310	
15	288	1.5219	
20	293	1.5128

71	344	1.4200	
80	353	1.4036	Boiling point
83	356	1.3981	

Data source: [21]

A similar equation for the density of pure nitric acid as a function of temperature, obtained in a narrow temperature range from 16 to 32°C is

$$\rho = 1.54918 - 0.001809t$$

where ρ is the density in g/cm^3 and t is the temperature in $^{\circ}\text{C}$, with a standard deviation in the density of 0.00028 g/cm^3 [46].

Density data in Table 10 for nitric acid with low water content have been gathered from secondary sources and the original source of these data is not known. The densities of pure nitric acid with 0–4% water were measured at 288 K (15°C) and are summarized in Table 11. See also [16]. The coefficient of thermal expansion of nitric acid can be derived from density data Table 12.

Table 10: Density of pure nitric acid, multiple literature data.

3.4.2 Density of Frozen Nitric Acid

The density calculated from XRD measurements, which were obtained at the freezing point of the acid (−41.6 °C), is 1.895 g/cm³ [48].

3.4.3 Pressure Dependence of the Specific Volume (Isothermal Compressibility)

The volumetric behavior of pure HNO₃ was determined at chemical and physical equilibrium between 344 and 444 K (160 and 340 °F) and for pressures up to 34 MPa (5000 psi) [49]. At 344 K (160 °F), approximately 30 h were required to reach chemical equilibrium under isochoric conditions, whereas only about 5 h were required at 361 K (190 °F). The bubble-point pressure varied from about 13.8 MPa to more than 17.2 MPa (2000 psi to more than 2500 psi). At 294 and 311 K (70 and 100 °F), the volumetric behavior of pure HNO₃, at physical equilibrium in the liquid phase, was determined for pressures up to 34 MPa (5000 psi). Data for the pressure dependence of the specific volume of nitric acid (isothermal compressibility) are listed in Table 13.

Table 13: Pressure dependence of the specific volume of nitric acid (isothermal compressibility).

Pressure, atm	Specific volume, cm ³ /g	
	at 21.1 °C	at 37.8 °C

3.4.4 Partial Molar Volume of Nitric Acid Mixtures

As shown in Figure 5, the specific volume of nitric acid as a function of water content is not a linear function [46, 51]. The excess specific volume is initially positive and becomes negative above a water mass fraction of 0.017.

The positive values of the excess volume suggest that at low concentrations, water behaves as a simple non-electrolyte, showing neither association nor attractive interaction with the solvent nitric acid.

The volumetric behavior of the system $\text{HNO}_3/\text{H}_2\text{O}$ under equilibrium conditions showed a distinct deviation from the behavior of ideal solutions [34, 52–54]. This included measurements of the specific volume at temperatures from 360.9 to 444.3 K (190 to 340 °F), for pressures up to 34.5 MPa (5000 psia) for 3 mixtures of water and nitric acid.

Data for the specific volume of nitric acid/water mixtures under conditions of chemical equilibrium are listed in Table 15.

For additional data on specific volume of nitric acid-water mixtures see also [18].

Figure 5: Specific volume of nitric acid with small water contents. (reproduced and modified from [46].)

3.5 Compressibility and Velocity of Sound of WFNA

3.5.1 Compressibility of WFNA

Data on the temperature dependence of the specific volume (isochoric compressibility) of nitric acid are listed in Table 16.

The following data on the isothermal compressibility of liquid nitric acid are only from a secondary source and the original source of these data could not be located (Table 17).

Table 16: Temperature dependence of the specific volume (isochoric compressibility) of nitric acid.

Temperature		Specific volume
K	°C	cm ³ /g
277.54	4.44	0.648866
283.1	10.0	0.653111
288.7	15.6	0.657544
294.2	21.1	0.660852
299.8	26.7	0.666346

5.51	54.4	107.6×10^{-6}	86.4×10^{-6}
8.62	85.1	93.3×10^{-6}	76.3×10^{-6}

Data source: [28]

3.5.2 Velocity of Sound in WFNA

The velocity of sound in liquid nitric acid can be used to calculate the adiabatic compressibility of this liquid (Table 18).

Other sources reported a velocity of sound of 1425 m/s at 289 K = 16 °C.

Table 18: Velocity of sound and specific heat ratio of technical grade nitric acid.

Composition, mass-%	Velocity of sound, m/s	Adiabatic coefficient
97.08% HNO ₃ , 0.22% NO ₂ , 1.91% H ₂ O, 0.79% Fe(NO ₃) ₃	1239.2	1.31
97.52% HNO ₃ , 0.28% NO ₂ , 2.11% H ₂ O, 0.09% Fe(NO ₃) ₃	1239.7	1.26

Data source: [57]

3.6 Viscosity of WFNA

One must differentiate between dynamic viscosity and kinematic viscosity. The SI physical unit of *dynamic viscosity* is the Pascal-second ($\text{Pa} \cdot \text{s}$), equivalent to $(\text{N} \cdot \text{s})/\text{m}^2$, or $\text{kg m}^{-1} \cdot \text{s}^{-1}$. The cgs physical unit for dynamic viscosity is the *poise*, abbreviated as Ps.

$$1 \text{ Ps} = 0.1 \text{ Pa} \cdot \text{s}$$

$$1 \text{ cPs} = 1 \text{ mPa} \cdot \text{s} = 0.001 \text{ Pa} \cdot \text{s}.$$

The SI unit of *kinematic viscosity* is m^2/s . The cgs physical unit for *kinematic viscosity* is the *stokes*, abbreviated as St. It is sometimes expressed in terms of centistokes (cSt).

$$1 \text{ St} = 1 \frac{\text{cm}^2}{\text{s}} = 10^{-4} \frac{\text{m}^2}{\text{s}}$$

$$1 \text{ cSt} = 1 \frac{\text{mm}^2}{\text{s}} = 10^{-6} \frac{\text{m}^2}{\text{s}}.$$

The following conversion factors are useful when bringing viscosity data from different sources to a common denominator:

$$1 \text{ cPs} = 1 \times 10^{-3} \text{ N s m}^{-2}$$

$$1 \text{ cPs} = 1 \text{ mPa} \cdot \text{s} = 0.001 \text{ Pa} \cdot \text{s}$$

$$1 \text{ cSt} = 1 \text{ mm}^2 \cdot \text{s}^{-1} = 10^{-6} \text{ m}^2 \cdot \text{s}^{-1}$$

The kinematic viscosity is the ratio of the dynamic (absolute) viscosity μ to the density of the fluid ρ . It is usually denoted by the Greek letter nu (ν). It is a convenient parameter when analyzing the Reynolds number which expresses the ratio of the inertial forces to the viscous forces.

The agreement among various viscosity data reported for pure nitric acid in the literature is not very good. In many cases the investigators (negligently or ignorantly) used a nitric acid of dubious purity. Quite often the acid decomposed extensively during the viscosity measurements. Table 19 is a random sampling of viscosity data reported in the literature, arranged by increasing temperature (not by year of publication as some of the other tables).

From an examination of the available data and of the work of Chanukvadze [63] on the nitric acid-water system up to 99.5% HNO_3 , it appears that the values of Briner, Suesz, and Favarger [19], of Naumova [59], and Mason, Petker, and Vango [43] (Table 20) are the most representative for the viscosity of pure nitric acid.

Table 19: Literature summary of dynamic viscosity data of nitric acid.

344.2	160.0	71.0	0.465	0.465
377.6	220.0	93.0	0.389	0.389

Data source: [28], p. 158

The temperature dependence of the viscosity of nitric acid between 291 and 343 K (18 and 70 °C) has been expressed by the following equation [66]:

$$\log \mu \times 10^3 = -0.9004 + 550.0/T$$

where μ is the viscosity in poise and T is the temperature in kelvin. The acid decomposed extensively during the viscosity measurements. The composition was not stated, but the acid appears to have contained excess nitrogen dioxide and possibly also water. The viscosity of HNO₃ at 273 K (0 °C) is 12.23 mPs [67].

Temperature dependency (293–353 K = 20–80 °C) of the viscosity of aqueous HNO₃ shows a maximum at 33 mol-% HNO₃, suggesting strong interaction and formation of the HNO₃•2H₂O dihydrate [68]. The dynamic viscosity of aqueous nitric acid as a function of HNO₃ concentration and temperature can be expressed by the equation

$$\log \eta = -1.6964 - 2.748(1 - c) + 2.719(1 - c)^2 + [457.39 + 1471.5(1 - c) - 1669.3(1 - c)^2]/T$$

for the concentration range $0.60 < c < 0.97$ mass fraction HNO₃ and by

$$\log \eta = -1.5712 + [235.98/(t + 130)] + 0.387c + 0.273c^2$$

for the concentration range $0 < c < 0.60$ mass fraction HNO₃, where c is the HNO₃ mass fraction, η is the viscosity in cPs, t is the temperature in °C, and T is the temperature in K. The viscosity increases with HNO₃ concentration and decreases with temperature. As illustrated in Figure 7, there is something wrong with these two equations because they do not connect at $c = 0.6$. They may connect at a mass fraction somewhat below 0.6. The average error in these equations is 5%.

The viscosity η of pure HNO₃ with a freezing point of 231.9–231.6 K (–41.2 to –41.5 °C) and a density of $d_0 = 1.5495 \text{ g/cm}^3$ was determined in the temperature range from 233 to 348 K (–40 to 75 °C) [69]. The viscosity η vs. temperature function was a straight line. The extrapolated values of η and the density data previously given

Figure 7: Dynamic viscosity of nitric acid solutions (image created by Schmidt 2019, based on data from [68])

were used in an attempt to determine the effect of temperature on the dissociation equilibrium of HNO_3 . Bachinski's equation

$$\eta = A/(t + \alpha)^3$$

gave a linear function with breaks at 243, 263, and 298 K (−30, −10, and 25 °C) and that of Frenkel,

$$\eta = Ae^{U/KT}$$

gave a linear function with breaks at −30 and −10 °C. The plots of fluidity ϕ vs. specific volume, and that of specific volume V vs. temperature were curved lines, the curvature of which increased with temperature. This behavior was attributed to the decomposition of solvate ions of HNO_3 .

3.7 Surface Tension of WFNA

Surface tension data for WFNA are listed in Table 23. The surface tension of pure HNO_3 at 293 K (20 °C) is 41.15 dyn/cm [71]. The surface tension of aqueous nitric acid as a function of HNO_3 concentration and temperature for the range $0 < c < 0.9$ can be expressed by the equation

$$\sigma = 72.75 - 5.57c - 24.55c^2 - 0.166(t - 20)$$

Table 23: Surface tension of pure nitric acid.

Temperature		Surface tension	
°C	K	dyn/cm	N/cm
0	273.15	43.56	0.000436
11.5	284.6	42.7	0.00043
20	293.1	41.2	0.00041
40	313.1	37.8	0.00038
78.2	351.3	31.5	0.00031

Data source: [70], p. 153–154, based on data from Miskidzhyan and Trifonov [17]

Conversion: 1 dyn = 10^{-5} N

where σ is the surface tension in dyn/cm, c is the mass fraction HNO_3 and t is the temperature in °C [68]. The surface tension decreases with increasing HNO_3 concentration and temperature.

3.8 Thermal Conductivity of WFNA

Thermal conductivity data for WFNA, gathered from several secondary sources where the original source of data is not always known, are summarized in Table 24 through Table 27.

Table 24: Thermal conductivity of pure nitric acid.

Composition: 95–97.5% HNO₃, <2% H₂O

Data source: [65]. Same data are shown in [10]

Extrapolating from the thermal conductivity of nitric acid/water solutions to 100% HNO₃ gave a thermal conductivity of $0.21 \text{ kcal m}^{-1} \text{ h}^{-1} \text{ °C}^{-1}$, or $5.8 \times 10^{-4} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ °C}^{-1}$, for the thermal conductivity of 100% nitric acid at 290.3 K (17.2 °C) [72]. Additional data on the thermal conductivity of a lesser grade technical nitric acid are in Table 27.

A graph in a NACA report shows the thermal conductivity as a function of temperature [26].

3.9 Heat Transfer Properties of White Fuming Nitric Acid

Although most rocket engines use the fuel instead of the oxidizer for regenerative cooling, in the past, occasionally both fuel and oxidizer (WFNA, RFNA, or NTO) have been used as coolants in bipropellant engines. For these applications it is of fundamental importance to know the heat transfer properties of these fluids [65, 73].

At Reynolds numbers from 55000 to 220000, initial acid temperatures of 283–341 K (10–68 °C), and pressures from 441 to 1138 kPa (4.35–11.2 atm = 64–165 psia) with heat fluxes between 21.3 and 230 W/cm² (5.1 and 55 cal cm⁻² s⁻¹ = 21.3 and 230 J cm⁻² s⁻¹) it was concluded that the heat transfer properties follow the Colburn equation, similar to the behavior of water at very high pressures [74, 75].

$$j = \frac{h}{\frac{m^*}{A} C_p (\text{Pr})^{2/3}} = 0.023 (\text{Re}^{-0.2})$$

where j is the Colburn modulus (a dimensionless number), h is the heat transfer coefficient, m^*/A is the mass flux per unit cross-sectional area, and C_p is the heat capacity. Pr and Re are the Prandtl and the Reynolds numbers. Continued circulation of the same acid in the test apparatus reduced the heat-transfer coefficient as much as 25%. Whether this was due to scale, dissociation, corrosion, or a combination of the three is not known. When the inside surface temperature of the tube exceeded the saturation temperature of the WTNA, the heat transfer rate and the pressure drop increased above

Figure 8: Heat flux density of WFNA nucleate boiling heat transfer at 0.448 MPa (65 psia) in 13.6-mm (0.537-in) I.D. Haynes 25 tube (reproduced and modified from [76]).

those predicted by the equation above. No satisfactory correlations of data could be obtained in the nucleate boiling regime. The nucleate boiling data were plotted with the heat-flux density against the temperature difference $t_s - t_{\text{bulk}}$ for constant mass flow rate in Figure 8. The curves were geometrically similar to those obtained by other investigators with fluids other than WFNA. For each mass flow rate the slope of the curve increased sharply as the surface temperature of the tube reached the saturation temperature, indicating that small increases in the surface temperature resulted in large increases in heat transfer rates. Shortly after entering a film-boiling region, the tube burned out.

A much simpler correlation for WFNA was obtained in continuation of this work [76]:

$$j = 0.030(\text{Re})^{-0.2}$$

In the same apparatus, tests with RFNA instead of WFNA resulted in much faster corrosion such that no reliable data could be obtained [77]. See also [78].

3.10 Critical Constants of WFNA

It is unlikely that measured data for the critical constants of nitric acid exist, because of the rapid decomposition of anhydrous nitric acid at elevated temperatures. Consequently, there is more than average uncertainty in the estimated values. The critical temperature of nitric acid was estimated at 624 K and the critical pressure was estimated as 94 atm by the methods of Gates and Thodos [79]. Critical compressibility is about 0.238. See also [80].

3.11 Solubility of Gases in Nitric Acid

The solubility of gases in nitric acid is of dual importance: First we need to know how much of the oxygen formed during the slow decomposition of WFNA during storage can remain in solution and how much of it will pressurize the ullage to unwanted and often dangerous overpressure. Secondly, pressurant gases dissolved in the oxidizers will affect their heat transfer coefficients in cooling jackets and cavitation in pumps in propellant feed systems. Henry's law at constant temperature may be written as

$$C_{\text{O}_2} = \alpha p$$

where C_{O_2} is the dissolved oxygen concentration in mol/L, α is the Henry's law coefficient and p is the pressure in atm. The solubility of dioxygen in WFNA or RFNA increased with temperature but decreased with increasing NO_2 or water content (Figure 9) [81, 82]. The Henry's law coefficient for solubility of dioxygen in pure nitric acid at 310.8 K (37.7 °C) was $5.55 \times 10^{-3} \text{ mol L}^{-1} \text{ atm}^{-1}$.

Figure 9: Effect of temperature on coefficient α in Henry's law for solutions of oxygen in nitric acid and mixtures of nitric acid with nitrogen dioxide or water (reproduced and modified from [82]).

The solubility of oxygen in 100% nitric acid at 298 K and 101 kPa was 0.0659 L gas under standard temperature (273 K) and pressure (0.101 kPa)(STP) per L of acid equal to 0.0437 L gas (STP) per g of acid [83]. The solubility decreased when water or dinitrogen tetroxide was added to the acid (Figure 10) and increased if the temperature was raised (Figure 11).

In Figure 11 the solid lines represent the same Robertson data as in Figure 9 above, while the dashed lines represent new data. Although smooth curves can be drawn as indicated by the dashed lines, it is necessary to ignore the points at 310.8 K (37.7°C) and to reverse the curvature of the solid lines. So far there is no theoretical basis for a choice of either type of curvature. It might even be a straight line; however, data for the solubility of oxygen, nitrogen, or helium in water show curvatures like the curves shown in solid lines, and therefore provide a basis for preference. While the results of

Figure 10: Solubility of oxygen in $\text{HNO}_3/\text{N}_2\text{O}_4$ and $\text{HNO}_3/\text{H}_2\text{O}$ mixtures (reprinted and adapted from [83] with permission. ©1955 American Chemical Society; permission conveyed through RightsLink)

Figure 11: Solubility of oxygen in $\text{HNO}_3/\text{N}_2\text{O}_4$ and $\text{HNO}_3/\text{H}_2\text{O}$ mixtures as a function of temperature (reprinted and adapted from [83] with permission. © 1955 American Chemical Society)

Sprague (dashed lines) indicate a somewhat lower solubility than those of Robertson, there is at least an order of magnitude agreement. It is unfortunate that data were not obtained at the same temperature, so that a direct comparison could be made.

At 293–353 K (20–80 °C) and 1–6 MPa (10–60 atm) the solubility of oxygen in 0–100% aqueous HNO_3 solutions is linearly related to temperature and pressure [84]. With an increase in temperature, the solubility of oxygen in $\leq 16\%$ HNO_3 decreased. In $>16\%$ HNO_3 , a temperature increase promoted a salting in of the oxygen with increased solubility. See also [85].

3.12 Nitric Acid as a Solvent

Mixtures of nitric acid with fuels can be used as explosives. Mixtures of nitric acid with alcohols are immediately detonable and not suitable as monopropellants. Solutions of some organic amine nitrates, mostly quaternary alkylammonium salts, in nitric acid have been tested as monopropellants (CAVEA-B, see *Encyclopedia of Monopropellants*, chapter “Nitric Acid or Perchloric Acid-Based Monopropellants”). Although tributyl phosphate and nitric acid, often in intimate contact during the reprocessing of nuclear reactor fuel elements, are not miscible, their emulsions are potentially detonable. Numerous explosions have occurred in nitrating reactors in the chemical industry where the solubility of reactants was underestimated. Nitric acid, dinitrogen tetroxide, and their mixtures are useful as media for inorganic reactions [86].

It is important to know the solubility of corrosion products in nitric acid, because once their solubility is exceeded, and mostly when the propellant tanks cool down, the salts may precipitate and clog filters, valves, and injector orifices. Unfortunately, data on solubility of iron(III) nitrate, $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ (CAS RN 10421-48-4) are available only in aqueous solutions containing from 0 to 59.9 mass-% HNO_3 at 293 K (20 °C) [87] and data for higher acid concentrations are lacking. With an increase in HNO_3 concentration, within the above range, the solubility of $\text{Fe}(\text{NO}_3)_3$ decreased sharply, dropping from 78.3–83.3 g/100 g to 13.0 g/100 g solution. At lower acid concentrations, $\text{Fe}(\text{NO}_3)_3$ had a tendency of to undergo hydrolysis.

Mixtures of nitric acid with acetic acid or acetic anhydride are often used for nitration of organic compounds where the traditional nitrating acid (nitric acid/sulfuric acid or nitric acid/oleum) would be too aggressive and result in unwanted side reactions. The properties of nitric acid/acetic acid solutions have been investigated. The melting point/concentration curve of the system $\text{HNO}_3/\text{CH}_3\text{COOH}$ is typical of a system where a compound is formed having a congruent melting point [88]. One eutectic occurs at 230.5 K (–42.6 °C), 33.3 mol-% HNO_3 , the other at 214.0 K (–59.1 °C), 80 mol-% HNO_3 . The compound, whose formula is $\text{CH}_3\text{COOH} \cdot \text{HNO}_3$, melts at 248.5 K (–24.6 °C). The viscosity-concentration curves at 273, 293, and 313 K (0, 20, and 40 °C) exhibit maxima (35.46 mPs) at 40–45 mol-% HNO_3 . The curves of surface tension σ vs.

composition of nitric acid/acetic acid mixtures were almost straight lines at all temperatures [71]. The heat of mixing of nitric acid and acetic acid goes through a maximum of 1158 cal/mol of mixture at 50 mol-% [89]. This shows chemical interaction and formation of an equimolar complex. Nitric acid and acetic acid form a low-boiling azeotrope which boils at 128.6°C and contains about 33 mol-% HNO_3 [90].

The variation of the electrical conductivity of solutions of ammonium nitrate (AN) in nitric acid and in nitric acid/dinitrogen pentoxide mixtures as a function of AN concentration was similar to that observed for many electrolytes in a variety of solvents, except when AN was dissolved in $\text{HNO}_3/\text{N}_2\text{O}_5$ solvents, where specific conductance decreased with increasing AN concentration [91]. The presence of additional nitrate anions suppressed the formation of nitronium NO_2^+ cations which are charge carriers in other nitric acid solutions. The addition of NH_4NO_3 stabilized concentrated, anhydrous HNO_3 .

3.13 Thermodynamic Properties of White Fuming Nitric Acid

The thermodynamic properties of WFNA are summarized in Table 28 through Table 34.

3.13.1 Heat Capacity of White Fuming Nitric Acid

3.13.1.1 Heat Capacity of Solid and Liquid White Fuming Nitric Acid

The heat capacity of pure nitric acid was measured calorimetrically in the temperature range 15–231.51 K (solid state) and 231.51–300 K (liquid state) [20]. The heat capacity of solid and liquid WFNA is tabulated in Table 28. These heat capacities of the liquid can be expressed conveniently by an empirical equation. The equation for the liquid represents the data in Table 28 between 230 and 300 K to better than 0.05%:

$$C_p = 25.64 + 1.427 \times 10^{-2}T - 4.090 \times 10^{-5}T^2$$

where C_p is the molar heat capacity in $\text{cal } ^\circ\text{C}^{-1} \text{ mol}^{-1}$ and T is the temperature in kelvin.

Table 29 gives heat capacity data of technical grade WFNA for a different temperature range. The isobaric heat capacities of WFNA and RFNA were determined at bubble point in a stainless-steel calorimeter, which was gold-plated for use with corrosive liquids [92]. The heat capacity measurements for WFNA were made in the temperature range from 316 to 336 K (110–145 °F). The nitric acid samples removed from the calorimeter after the heat capacity measurements showed evidence of significant corrosion. It appears that the heat capacity of liquid HNO_3 does not change much over the temperature range of interest (Figure 12).

3.13.1.2 Heat Capacity of White Fuming Nitric Acid Vapor

The heat capacity of nitric acid vapor as a function of temperature can be calculated from the following polynomial Shomate equation which was obtained from NIST Chemistry WebBook [15]:

$$C_p^\circ = A + B \times \tau + C \times \tau^2 + D \times \tau^3 + \frac{E}{\tau^2}$$

where C_p is the molar heat capacity in J mol⁻¹ K⁻¹, τ is the temperature in kelvin divided by 1000 and A, B, C, D, and E are constants listed in Table 30 for two different temperature ranges. One must note that HNO₃ is unstable at temperatures above 400 K and the column for the higher temperature range 1100–6000 K is only of academic inter-

Figure 12: Heat capacity of liquid (95–97% HNO₃) nitric acid (reproduced and modified from [10])

Table 30: Thermodynamic property polynomial equation coefficients for nitric acid vapor.

Temperature, K	298–1200	1200–6000
A	19.63229	97.45959
B	153.9599	5.429577

G	247.7049	343.8051
H	-134.3060	-134.3060

Data source: [93]

est. It is not very practical to list thermodynamic data for a compound that is unstable at the temperature range listed. It would be much more important to have accurate thermodynamic data for the liquid mixtures of nitric acid with dinitrogen tetroxide.

Some HNO₃ vapor heat capacity data calculated with above equation are summarized in Table 31. Heat capacity data for HNO₃ vapor calculated from IR measurements can be expressed by the equation [94]:

$$C_p = 2.88 + 4.047 \times 10^{-2}T - 2.407 \times 10^{-5}T^2$$

where C_p is the molar heat capacity in cal °C⁻¹ mol⁻¹ and T is the temperature in kelvin.

Table 31: Heat capacity of nitric acid vapor.

3.13.2 Heat of Formation of White Fuming Nitric Acid

Standard enthalpy of formation (ΔH)₂₉₈ data for liquid and gaseous nitric acid are listed in Table 32.

Table 32: Standard enthalpy of formation (ΔH)₂₉₈ of nitric acid.

Physical state	Standard enthalpy of formation (ΔH_f) ₂₉₈			Data source	Year	References
	kJ/mol	kcal/mol	cal/g			
Gas	-134.31	-32.1	-509.4	NIST Chemistry WebBook	1998	[93]
Gas	-134.360 ± 0.5	-32.113 ± 0.120		Dorofeeva et al.	2003	[95]
Gas	-134.196	-32.073	-509	PEPCODED.DAF	1986	[96]
Liquid	-173.47	-41.46	-658	PEPCODED.DAF	1986	[96]
Liquid	-171.58	-41.01	-650.8	JPLCODED.DAT	1988	[96]

Molecular mass: 63.0128 g/mol [10]

In the past, the enthalpy of formation of nitric acid was determined from data on equilibria involving HNO₃. The JAN(N)AF thermochemical tables and the compilation published by Gurvich et al. [97] provide an exhaustive analysis of these experimental data, resulting in values from -129.7 to -136.7 kJ/mol for $\Delta H_f^\circ \text{HNO}_3(\text{G})$ at 298.15 K. The value adopted by [95], -134.360 ± 0.5 kJ/mol, is the average of experimental values. This value is in good agreement with the results of theoretical calculations based on *ab initio* calculation and the isodesmic reaction procedure -133.3 kJ/mol. A similar

value of -132.7 kJ/mol was calculated by the composite G3 method using the GAUSSIAN 98 system of programs.

The generally accepted standard enthalpy of formation of nitric acid vapor at 298 K is -134.31 kJ/mol [93]. The enthalpy of formation of nitric acid vapor as a function of temperature can be calculated from the following polynomial equation:

$$H^\circ - H^\circ_{298.15} = A \times \tau + \frac{B \times \tau^2}{2} + \frac{C \times \tau^3}{3} + \frac{D \times \tau^4}{4} - \frac{E}{\tau} + F - H$$

where $H^\circ - H^\circ_{298.15}$ is the excess enthalpy in kJ/mol , τ is the temperature in kelvin divided by 1000 and A, B, C, D, E, F, and H are constants listed in Table 30 for two different temperature ranges. It is disappointing that NIST WebBook [93] does not give any data for liquid nitric acid.

3.13.3 Heat of Fusion of White Fuming Nitric Acid

The heat of fusion of nitric acid is $10.472 \pm 0.008 \text{ kJ/mol} = 2.503 \pm 0.002 \text{ kcal/mol}$, determined calorimetrically [20].

3.13.4 Heat of Evaporation of White Fuming Nitric Acid

The heat of evaporation $\Delta H_{\text{evap.}}$ of nitric acid at the normal boiling point is $35.85 \text{ kJ/mol} = 8.569 \text{ kcal/mol}$ and the heat of evaporation $\Delta H_{\text{evap.}}$ at $298 \text{ K} = 25^\circ\text{C}$ is $39.13 \text{ kJ/mol} = 9.353 \text{ kcal/mol}$. Literature data on the heat of evaporation of nitric acid are summarized in Table 33.

Table 33: Heat of evaporation of nitric acid.

Temperature		Heat of evaporation		Authors	Year	References

^a Calculated from vapor pressure data

^b Average calorimetric value

In a critical review, the value of 7.80 kcal/mol at 20 °C was rejected as unreliable and 9.426 kcal/mol was considered the best data as of 1960. The heat of evaporation at 298 K could also be calculated from the differences in enthalpy of formation of the liquid and the vapor. Differences in the heat of formation data of liquid and vapor HNO_3 in Table 32 would indicate $658\text{--}509\text{ cal/g} = 149\text{ cal/g} = 9.388\text{ kcal/mol}$.

The heat of evaporation in $\text{HNO}_3/\text{H}_2\text{O}$ mixtures with $>60\%$ HNO_3 remains constant and is similar to that of pure water. Some of the vapor pressure data indicate a hydrate with the composition $2\text{HNO}_3 \cdot 3\text{H}_2\text{O}$ [100]. The vapor pressure has a minimum at this composition. Others interpreted this as a mixture of the well-known monohydrate and trihydrate.

3.13.5 Entropy of White Fuming Nitric Acid

The structural, spectroscopic, and thermochemical properties of HNO_3 vapor have been re-examined and recalculated and revised ideal gas thermodynamic tables were published [95]. The revisions were based on new spectroscopic information and made use of improved calculation methods. Compared to previous calculations, the entropy at 298.15 K $S^\circ(298.15\text{ K})\ 266.860 \pm 0.7\text{ J K}^{-1}\text{ mol}^{-1}$ (Table 34 and 35) is unchanged for $\text{HNO}_3(\text{G})$, but the high temperature values ($T > 4000\text{ K}$) are significantly different. The original publication contains tabulated data for up to 6000 K which is only of the-oretical value because at that temperature nitric acid ceases to exist. The calculated entropy value at 298.15 K which is $266.8\text{ J K}^{-1}\text{ mol}^{-1}$ is in close agreement with the value of $S^\circ(298.15\text{ K})$ obtained from calorimetric data which is $266.2\text{ J K}^{-1}\text{ mol}^{-1}$.

Gas	266.860 ± 0.7	63.78 ± 0.17	Dorofeeva et al.	2003	[95]

The standard entropy of formation of nitric acid vapor at 298 K and 101 kPa is $266.39 \text{ J mol}^{-1} \text{ K}^{-1}$ [93]. The entropy of nitric acid vapor as a function of temperature can be calculated from the following polynomial equation:

$$S^\circ = A \times \ln(\tau) + B \times \tau + \frac{C \times \tau^2}{2} + \frac{D \times \tau^3}{3} - \frac{E}{2 \times \tau^2} + G$$

where S° is the entropy in $\text{J mol}^{-1} \text{ K}^{-1}$, τ is the temperature in kelvin divided by 1000 and A, B, C, D, E, and G are constants listed in Table 30 for two different temperature ranges.

Entropy data for condensed phase nitric acid are scarce. One source of information [20] lists it as $S_{298} = 155.6 \text{ J mol}^{-1} \text{ K}^{-1} = 37.19 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$ for the liquid at 298 K (25°C) and $82.37 \text{ J mol}^{-1} \text{ K}^{-1} = 19.686 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$ for the solid at melting point (231.51 K).

3.14 Molecular Properties, Structure, Dipole Moment, and Molecular Orbital Calculations

3.14.1 Molecular Structure of Nitric Acid

The analysis of electron diffraction patterns and the microwave spectrum indicated that the molecule of nitric acid in the gas phase is planar. The molecular structure of nitric acid is illustrated in Figure 13.

Figure 13: Molecular structure of nitric acid $1 \text{ pm} = 10^{-9} \text{ m} = 10 \text{ \AA}$

Other estimates for the atomic distances and bond angles in the nitric acid molecule based on electron diffraction measurements are $\text{N}-\text{O} 1.22 \pm 0.02 \text{ \AA}$, $\text{N}-\text{OH} 1.41 \pm 0.02 \text{ \AA}$, $\angle \text{O}-\text{N}-\text{O} 130 \pm 5^\circ$, $\angle \text{O}-\text{N}-\text{OH} 115 \pm 2.5^\circ$. Similar results were derived from XRD measurements: $\text{N}-\text{O} 1.24 \pm 0.025 \text{ \AA}$, $\text{N}-\text{OH} 1.30 \pm 0.025 \text{ \AA}$, $\angle \text{O}-\text{N}-\text{O} 134 \pm 3.5^\circ$, $\angle \text{O}-\text{N}-\text{OH} 113 \pm 5^\circ$.

Other molecular structure data from a recent review of data [95] are:

$r(\text{O}-\text{H})$	$0.9416 \pm 0.003 \text{ \AA}$	$\text{H}-\text{O}-\text{N}$ 102.660.3°
$r(\text{N}-\text{OH})$	$1.4106 \pm 0.002 \text{ \AA}$	$\text{O}-\text{N}-\text{O}$ <i>cis</i> 115.760.2°
$r(\text{N}-\text{O})$	<i>cis</i> $1.2136 \pm 0.002 \text{ \AA}$	$\text{O}-\text{N}-\text{O}$ <i>trans</i> 114.160.2°
$r(\text{N}-\text{O})$	<i>trans</i> $1.1986 \pm 0.002 \text{ \AA}$	

There may be a resonance between three possible structures I, II, and III with structure III being less likely due to the proximity of two identical charges on the two central atoms (Figure 14).

Figure 14: Resonance structures of the HNO_3 molecule

Two molecules of HNO_3 may associate in solutions or in the vapor phase, forming a dimer. Self-association was quantitatively studied by cryoscopy and infrared spectrometry at different temperature of HNO_3 solutions in CCl_4 [101]. From studies of the surface tension and parachor of liquid nitric acid, association of HNO_3 molecules was inferred, the dimers having the structure

Nitric acid dimer structure

Any valence model for nitric acid vapor must account for the large $\text{O}-\text{N}-\text{O}$ angle and the high barrier to rotation about the $\text{N}-\text{OH}$ bond. Both these facts may be explained by intramolecular hydrogen bonding. The composition $(\text{HNO}_3)_2$ would also be identical with hydrated nitronium nitrate $[\text{NO}_2^+][\text{NO}_3^-][\text{H}_2\text{O}]$ which is the active nitrating agent in anhydrous nitric acid and mixed acid. The nitric acid monohydrate $\text{HNO}_3 \cdot \text{H}_2\text{O}$ may also have the structure of an ortho nitric acid $\text{ON}(\text{OH})_3$ in analogy to phosphoric acid [100].

3.14.2 Crystal Structure of Frozen Nitric Acid

The crystal unit cell of frozen nitric acid contains 16 molecules of HNO_3 and has the dimensions $a = 16.23 \pm 0.05 \text{ \AA}$, $b = 8.57 \pm 0.03 \text{ \AA}$, $c = 6.31 \pm 0.01 \text{ \AA}$ [48]. The space group symmetry is $P2_1/a - C_{2h}^5$ in the monoclinic system, with the angle $\beta = 90^\circ$. The XRD density calculated from these values, which were obtained at the freezing point of the acid (-41.6°C), is 1.895 g/cm^3 .

3.15 Dipole Moment of Nitric Acid

Microwave measurements predicted the dipole moment of nitric acid to be $\mu = 2.17 \pm 0.02$ Debye units.

3.16 Optical Properties of White Fuming Nitric Acid

3.16.1 Infrared Absorption Spectra of Nitric Acid

Due to the troublesome formation of nitric acid as an atmospheric pollutant, most spectroscopic studies were done for nitric acid vapor and only relatively few studies were done for liquid or even frozen nitric acid.

The IR spectra of nitric acid have practical interest. They can be used to ascertain the purity of nitric acid samples and detect nitric acid as a constituent of atmospheric smog and stratospheric clouds in polluted atmospheres. Nitric acid may form and needs to be detected as an intermediate in the decomposition of organic nitrate esters, where hundreds of those compounds have been evaluated and a dozen of those are being used as rocket propellant ingredients. Spectroscopy of decomposing alkyl nitrates revealed the short-lived presence of nitric acid. The disappearance of HNO_3 can be measured by IR absorption in kinetic studies of nitration reactions that lead to nitrate esters or nitro compounds.

3.16.1.1 Infrared Spectra of Nitric Acid Vapor

The pure rotational absorption spectrum of nitric acid vapor has been measured by Fourier-transform infrared (FTIR) spectroscopy in the region $8\text{--}40 \text{ cm}^{-1}$ at a resolution of 0.05 cm^{-1} [102]. The structure of the spectrum corresponds closely to the normally forbidden perpendicular pure rotation band of a symmetric top. In the limit of a planar oblate near symmetric rotor, the band simply shows a series of equispaced sharp absorption lines.

The vibration-rotation spectrum of nitric acid of the bands ν_5 and $2\nu_9$ has been recorded between 855 and 915 cm^{-1} , with a resolution of 0.05 cm^{-1} [103].

High resolution spectra in the region of the ν_2 band of nitric acid have been obtained for selected portions of the HNO_3 spectrum using tunable diode laser techniques, showing continuous spectra from 1718.97 to 1729.57 cm^{-1} , with a spectral reso-

lution of $\leq 0.001 \text{ cm}^{-1}$ (30 MHz) [104]. The IR spectrum of the ν_2 band of nitric acid has been measured with a tunable diode laser in the wave number interval from 1690 to 1727 cm^{-1} [105]. Over 210 transitions have been measured in the millimeter and submillimeter spectral region [106]. Additional information on the IR spectra of nitric acid is found in [107–109]. The data necessary to reproduce the spectrum of HNO_3 at temperatures up to 300 K in the $1\text{--}7000 \text{ cm}^{-1}$ range has been stored in a variety of formats, including a line list in the ExoMol format [110]. The list contains transitions involving rotational quantum number J up to 70 for 9×10^6 vibration-rotation energy levels belonging to 1715 vibrational states and associated transitions probabilities. In total the line list contains about 2 billion transitions.

Isotope Studies of Infrared Spectra of Nitric Acid

Isotope substitution of hydrogen in nitric acid with deuterium allowed the assignment of fundamental vibrations in the IR spectrum of nitric acid vapor as shown in Table 36 [94]. This work also identified the barrier height against internal rotation around the N–OH axis and derived thermodynamic functions.

Table 36: Fundamental vibrations in the IR spectrum of HNO_3 and DNO_3 .

a''	465	a''	365

Data source: [94]

The vibrational spectra of four isotopic nitric acid molecules including ^{15}N and D isotope labeling have been obtained in the vapor and solid phases and compared to Raman spectra of normal nitric acid [111, 112]. The potential barrier against internal rotation of the hydroxyl group has been calculated to be $32.6 \pm 0.4 \text{ kJ/mol} = 7.8 \pm 0.1 \text{ kcal/mol}$ in both the H and D acids. The IR spectrum of nitric acid vapor at two different pressures, measured in a 10.2-cm path length cell, is shown in Figure 15.

A similar spectrum is available from the same source for solid nitric acid at the temperature of liquid nitrogen. See also [113].

Figure 15: IR spectrum of nitric acid vapor at pressures of 20 and 50 mm Hg (from [111])

Infrared Spectra of Liquid Nitric Acid

The IR absorption spectrum of liquid 99.2% HNO_3 held between silver chloride windows with a path length of $2\mu\text{m}$ shown in Figure 16 is similar to that of nitric acid vapor [114]. There are only very few near-IR spectra published in the 1000–2000 nm range where the Military Specification for N_2O_4 measures the water content.

Table 37 is a comparison of the frequencies of IR vapor, IR liquid, and Raman liquid absorption/fluorescence spectra.

Infrared Spectra of Nitric Acid Hydrates

The freezing point curve and other physical property measurements in the $\text{HNO}_3/\text{H}_2\text{O}$ binary system indicate the formation of hydrates with various $\text{HNO}_3 : \text{H}_2\text{O}$ ratios. This is confirmed by examining the IR spectra in the liquid phase. Vibrational spectroscopy and XRD have been applied to investigate the crystallization of concentrated amorphous nitric acid ($0.5 \leq x \leq 0.95$) [115]. Crystalline nitric acid monohydrate ($\text{HNO}_3 \cdot \text{H}_2\text{O}$) is the major hydrate phase detected together with traces of metastable nitric acid dihydrate ($\text{HNO}_3 \cdot 2\text{H}_2\text{O}$) and pure crystalline nitric acid. XRD showed nitric acid monohydrate has a highly symmetrical structure, which is confirmed by IR, Raman, and inelastic neutron scattering spectra. The NIST Chemistry WebBook [93] shows only IR spectra of 14, 23.3, and 35% HNO_3 aqueous solutions, which are not very characteristic.

Infrared Spectra of Solid Nitric Acid

Ab initio calculations and IR spectroscopy have been used to study of the structure and vibrational frequencies of crystalline nitric acid [116]. The crystallographic data on the unit cell structure have been refined and the vibrational frequencies of the crystal have been determined in the calculation. In the higher frequency range, the experimental spectra showed a broad absorption band with 2 maxima at about 3100 and 2980 cm^{-1} assigned to the stretching of the $\text{O}'-\text{H}$ bond, ν_1 . Proposed assignments to the predom-

inant molecular vibrations in the range between 3487 and 426 cm^{-1} were given for the strongest absorption bands. The calculation provided an indication of the position of the H atoms in the crystal. The average O'—H bond distance is $1.013 \pm 0.009 \text{ \AA}$ and the NOH angle is $105.490 \pm 0.025^\circ$. See also [117, 118].

3.16.2 Raman Spectra of Nitric Acid

Raman spectra of the equimolecular mixture $\text{HNO}_3 \cdot \text{H}_2\text{O}$ in the liquid and glassy frozen states in the range from 4000 cm^{-1} down to 50 cm^{-1} indicated the presence of at least 4 species: **(1)** The free molecular association $\text{H}_2\text{O} \cdots \text{HONO}_2$ with $\nu\text{OH}(\text{H}_2\text{O}) = 3550 \text{ cm}^{-1}$ (3440 cm^{-1}) and $\nu\text{OH}(\text{HNO}_3) = 2930 \text{ cm}^{-1}$ (2915 cm^{-1}) in the liquid and the glassy state, respectively. **(2)** The free ionic pair $(\text{H}_2\text{OH})^+ \cdots (\text{ONO}_2)^-$ that give a splitting ($\Delta\nu = 170 \text{ cm}^{-1}$) of the $\nu_3\text{NO}_3^-$ vibration. **(3)** Free HNO_3 molecules: $\nu\text{NOH} = 940$ and 950 cm^{-1} in the liquid and the glassy state. **(4)** The nitric acid trihydrate: $\text{H}_7\text{O}_3^+\text{NO}_3^-$ with νOH between 3100 and 3300 cm^{-1} [119, 120].

At very high pressures up to 50 GPa, the association of nitric acid to form dimers and higher associates becomes more pronounced as is evident from changes in the Raman spectra [121] and nitric acid will begin to crystallize. Like common practice in identifying IR vibrations, isotope substitution allows investigators to identify Raman-active molecular vibrations and species that are in equilibrium with nitric acid as it associates or dissociates [122].

3.16.3 Ultraviolet Absorption Spectra of Nitric Acid

The UV absorption of nitric acid is difficult to determine because the molecule photolyzes even while the measurement is in progress. Quantitative measurements were made of the pure HNO_3 vapor absorption spectrum in the 1700–2636 $\text{\AA}$ wavelength interval at 295 K (22°C) [123]. Absorption coefficients were determined using 6 absorption cell lengths between 0.1 and 10.0 cm, and numerous gas pressures in the 40–6687 Pa (0.0004–0.066 atm) range. An example absorption spectrum obtained with a 5-cm cell is shown in Figure 17. The maximum of absorption is near 1800 $\text{\AA}$. The results were used to estimate the absorption of UV radiation by stratospheric HNO_3 , which is an air pollutant and smog ingredient.

The ultraviolet (UV) absorption spectra of amorphous and crystalline $\text{H}_2\text{O}/\text{HNO}_3$ films were measured in a cold cell. Pure HNO_3 films showed a broad absorption peak with a maximum absorbance at $\lambda \approx 1950 \text{ \AA}$ [124]. Figure 18 shows a comparison of UV spectra of HNO_3 in the form of a solid thin film, liquid, and vapor. The absorbances of amorphous $\text{H}_2\text{O}/\text{HNO}_3$ films were very broad and peaked at $\lambda = 1960\text{--}1980 \text{ \AA}$. The major absorbing species in crystalline HNO_3 hydrates is the nitrate ion NO_3^- .

Both nitronium and nitrate participate in ionic equilibria in the system water-nitric acid-nitrogen pentoxide at compositions near 100% HNO_3 . It was suggested that the nitronium ion might be responsible for some of the absorption at 2565 $\text{\AA}$. Since the

Figure 17: UV Absorption of nitric acid vapor in a 5-cm cell (reprinted and modified from [123], with permission granted by © 1974 The Optical Society)

Figure 18: Comparison of UV spectra of HNO_3 in three different forms (reproduced and modified from [124])

nitrate ion is a relatively weak absorber with a maximum at 3020 Å, it would not contribute appreciably to the maximum for the pure acid.

3.16.4 Index of Refraction of Nitric Acid

The index of refraction of 100% HNO₃ is $n_D = 1.3910$ at 308 K (35 °C) and 1.4030 at 278 K (5 °C) [71]. Another data point is $n_D = 1.3970$ at 297 K (24 °C) [90].

3.17 Microwave Absorption Spectra of Nitric Acid

Microwave measurements dimensions indicated that the O—N—O angle is closer to 135° than the 130° value found by electron diffraction. For a symmetric or nearly symmetric rotor, the relative intensities of the *P*, *Q*, and *R* branches in the IR spectrum are known approximately for various orientations of the vibrational dipole moment of inertia. The greater O—N—O angle is more consistent with the observed band shapes and assignments in the IR spectrum of nitric acid vapor. Isotope labeling gave the following results: O—H = 0.964 Å, (H)O—N = 1.406 Å, *cis*-N—O = 1.211 Å, *trans*-N—O = 1.199 Å, $\angle$ HON = 102°9', $\angle$ *cis*-ONO(H) = 115°53', $\angle$ *trans*-ONO(H) = 113°51', and O...O (NO₂ group) = 2.184 Å. This determination clearly demonstrated a 2° tilt of the NO₂ group away from the hydrogen atom and exact planarity of the nitric acid molecule [125]. From these microwave measurements, the total dipole moment of nitric acid was predicted to be $\mu = 2.17 \pm 0.02$ Debye units.

3.18 Electrical Properties of White Fuming Nitric Acid

The chemistry and electrical conductivity of 100% nitric acid is governed by the self-dissociation equilibrium:

Solvation of the water and nitrate ion by nitric acid is strong. Clearly, addition of one of the components on the right-hand side of equation is expected to suppress the concentration of the other two. For instance, the addition of water is seen to reduce the conductivity of the nitric acid as the concentration of NO₂⁺ + NO₃[−] are reduced. A conductivity minimum is observed at ca. 4 mass-% water, and the increase in conductivity with further water addition is attributed to the production of the hydroxoniun ion according to:

As shown in Figure 19, the conductance of the HNO₃/H₂O system increased with an increase in the mass fraction of HNO₃ and reached a maximum at about 0.29 mass frac-

Figure 19: Specific conductance of nitric acid/water at 273 K and atmospheric pressure as a function of nitric acid content (reproduced and modified from [126])

tion HNO₃ [126, 127]. Between 0.30 and 0.97 mass fraction the conductance decreased and reached a minimum at 0.97 mass fraction HNO₃. Below 0.97 mass fraction HNO₃, hydrogen and nitrate ions are the predominant conducting species. In the range 0.97–1.00 mass fraction nitric acid, the conductance again increased. In this latter range, studies of the Raman spectra of the system indicated that HNO₃ undergoes self-ionization to yield nitronium ions (NO₂⁺) and nitrate ions (NO₃⁻) according to the equation

It is evident from this expression that the self-ionization of nitric acid is suppressed by the addition of water. Thus, the reduction of conductance of pure nitric acid upon the addition of water can be explained. Similar electrical conductivity measurements for binary HNO₃/N₂O₄ and ternary HNO₃/N₂O₄/H₂O mixtures are shown in the RFNA Chapter.

Literature data for the electrical conductivity of pure nitric acid are summarized in Table 38 and 39. All measurements are consistent in showing that the temperature dependence of the specific conductance is very small. Electrical conductivity numbers reported by [128] seem to be totally out of range when compared to other data.

3.19 Magnetic Properties of White Fuming Nitric Acid

Nitric acid is a diamagnetic substance. The specific magnetic susceptibility of anhydrous nitric acid at room temperature measured by Pascault and Chedin [131] was -0.3168×10^{-6} cgs units and the molar magnetic susceptibility was -19.9×10^{-6} cgs units. Other magnetic susceptibility data reported in the literature were obtained in aqueous nitric acid solutions and may be less reliable.

4 Chemical Properties of WFNA

Nitric acid is a powerful oxidizer which enables spontaneous ignition of many organic substances as soon as it comes in contact with them. This property, called “hypergolic ignition” is the main reason why nitric acid has been used as a rocket propellant for a long time. In addition, nitric acid can be used as an oxidizer also with non-hypergolic fuels, such as kerosene or JP-4, but that would require a separate ignition mechanism and lacks repeated startability. The chemical properties of three types of nitric acid are discussed here: WFNA, RFNA (IRFNA), and mixed acid (MA). Chemical properties of interest for the rocket application of these oxidizers are: storage stability, thermal stability, corrosion, and methods of analysis and detection.

4.1 Reactions of WFNA

4.1.1 Reactions of Nitric Acid with Inorganic Compounds

The reaction of HNO_3 with H_2O in aqueous solutions forming hydrates can barely be called a chemical reaction, but the hydrate formation is evidenced by peritectic points in the melting point diagram of the $\text{HNO}_3/\text{H}_2\text{O}$ system (Figure 1). The formation of nitric acid hydrates has already been discussed in various sections of this chapter. Occasionally additional hydrates are discovered [132]. The determination of the dissociation constant of nitric acid in diluted solutions in water is difficult because nitric acid is not completely dissociated as one would expect for a strong acid, but some of the undissociated acid is bound in the form of hydrates. The acid constant pK_a of nitric acid in 1-M solutions was estimated as -0.9 ± 0.2 .

4.1.2 Reactions of Nitric Acid with Organic Compounds

There are two types of reactions of nitric acid with organic compounds that are of importance for rocket propellants: **(1)** nitration reactions for the preparation of nitro compounds and nitrate esters (hopefully not leading to ignition in the reaction vessel), and **(2)** hypergolic ignition reaction with hypergolic fuels, mostly alkylamines, alkylhydrazines or unsaturated hydrocarbons. Nitration reactions are discussed in *Encyclopedia of Oxidizers*, chapter “Nitrate Esters” on the preparation of nitrate esters. One must keep in mind that any mixture of nitric acid with organic compounds is potentially detonable and adequate precautions must be taken when handling such mixtures.

4.2 Autodissociation of Nitric Acid

Autodissociation (self-ionization) of nitric acid is responsible for the relatively high electrical conductivity of pure nitric acid. Pure 100% nitric acid dissociates partly into dinitrogen pentoxide and water:

Dinitrogen pentoxide is completely dissociated in nitric acid solutions at low temperatures into stably solvated nitronium (NO_2^+) and nitrate (NO_3^-) ions, while the water exists mainly as a solvated molecular species. The absence of the known Raman frequencies of molecular nitrogen pentoxide demonstrates its complete dissociation into these ions. The complete self-ionization of nitric acid can consequently be expressed, apart from solvation, by the equation:

The equilibrium constant for this process, defined in terms of mol fractions and activity coefficients, was calculated for several temperatures using cryoscopic and conductance data (Table 40).

Table 40: Equilibrium constant for self-ionization of nitric acid.

Temperature		Equilibrium constant $\times 10^5$	Authors	Year	References
K	°C				
233	−40	2.44	Dunning and Nutt	1951	[23]
253	−20	1.602	Lee and Millen	1956	[129]
263	−10	0.930	Lee and Millen	1956	—
298	25	0.280	Taylor, Lyne, and Follows	1951	[62]

While the mechanism of the self-ionization of nitric acid is due to self-dehydration, about 10–15% of the process could be attributed to autoprotolysis

The extensive evidence available in favor of the former mechanism of self-ionization comes from cryoscopic measurements [133]. It is estimated that in analytically anhydrous nitric acid at 233 K (−40 °C), about 3–4% of the original acid is dissociated to give 1.2% of nitronium ion, 1.7% of nitrate ion, and 0.5% water.

Evidence for the presence of water in analytically anhydrous nitric acid has been obtained by finding two very weak bands in the Raman spectrum of pure nitric acid, at

2980 and 3550 cm^{-1} , which belong to a hydrogen bonded solvate of water. The ionization of water in nitric acid solutions, which could take place according to the equation:

occurs only to a small extent. This has been substantiated by the observation that the electrical conductivity of nitric acid solutions containing as much as 8–10 mass-% of water is smaller than that of the pure acid.

The addition of up to 23% of dinitrogen pentoxide to nitric acid has only a negligible effect on the total vapor pressure, a behavior suggesting that the ionic species formed by the dissociation of dinitrogen pentoxide are strongly solvated.

4.3 Analysis of White Fuming Nitric Acid

Because WFNA is in a constant state of decomposition and changes its composition during storage, it is important to analyze it periodically to make sure that the contents of the container are still what it says on the label. In addition, the acid is hygroscopic and might absorb moisture from the air or it might become contaminated by corrosion products.

Analytical methods are needed for the determination of HNO_3 assay and H_2O , NO_2 , HF contaminants, and additives. In the United States, RFNA must meet the requirements of MIL-PRF-7254G – Propellant, Nitric Acid, but there is no corresponding military specification for WFNA. The WFNA being used for making RFNA is not covered by a specification of its own. Lesser concentrations of nitric acid are covered by Federal Specification O-N-350B, Nitric Acid, Technical (Sep 1985). The methods for analysis of NO_2 and H_2O in RFNA listed in MIL-PRF-7254G can also be used for WFNA at lower concentrations. See also [134].

4.3.1 Determination of Water Content of White Fuming Nitric Acid

The determination of water in WFNA can be performed by IR spectrophotometric or volumetric methods.

The addition of water to pure nitric acid caused a weak absorption band to develop at 0.97 μm . The strength of the band increased with increasing concentrations of water. Absorption bands of pure liquid water at 1.92 and 3.0 μm occurred also in 95% nitric acid, almost unaffected except for a slight shift in wavelength and some peak sharpening. Liquid water has absorption bands at approximately the following wave lengths: 0.98, 1.18, 1.45, 1.74, 1.79, 1.96, and 2.79 μm . No absorption bands which can be attributed to nitrogen dioxide have been reported between 1 and 2 μm . This is important because fuming nitric acid often contains nitrogen dioxide.

One IR spectrophotometric method for determination of water content in white fuming nitric acid used the absorption band of O—H at $1.423\mu\text{m}$, but it tended to give high results, because some of water is the result of autodissociation of nitric acid [135]:

Because this equilibrium is affected by the NO_3^- content, which in turn is affected by the N_2O_4 and NO_2 concentration, by way of the equilibrium

the indicated water content is dependent on the NO_2 content of the acid. A correction must be applied that can be looked up in the following graph, unless both water and NO_2 concentrations are very small (see Figure 20). Corrections can be looked up for acids containing up to 20% NO_2 . Nitrate salts that are dissolved in the acid will also affect the water readings.

Figure 20: Correction for IR spectrophotometric determination of water in nitric acid (reprinted and modified from [135] with permission from © 1956 American Chemical Society; permission conveyed through RightsLink)

Another method for determination of water in white or red fuming nitric acid is the volumetric titration using the Karl Fischer reagent [136, 137].

In another variant of this method, the acid was first slowly neutralized by addition of a 2:1 volume ratio mixture of pyridine and dimethylformamide to avoid interfering reactions with the reagent [138]. An excess of Karl Fischer reagent was added and then

back-titrated with standard water in methanol titrant. In the absence of dissolved salts an accuracy of 1% relative could be achieved. Nitrogen dioxide concentrations up to 1.5 mass-% did not interfere.

Wet chemical methods are cumbersome and not very accurate. For acceptance tests of WFNA in the field, an electric conductometric method would be preferred. Several conductometric methods have been developed and field-tested for that purpose [139].

At a given temperature the conductance of a sample of fuming nitric acid, together with the conductance of a duplicate sample saturated with anhydrous potassium nitrate, gives enough information to determine the composition of the sample [140, 141]. Values of the specific conductance of saturated solutions of potassium nitrate in fuming nitric acid were obtained at 273 K for various fuming nitric acid mixtures, and the resulting data necessary for utilizing this conductometric method of analysis in the composition range 0–12 mass-% NO_2 , 0–10 mass-% water were presented in graphical and tabular form. By this method NO_2 can be determined to within $\pm 0.3\%$ on an absolute basis and water can be determined to within ± 0.3 mass-% in the composition range studied. These conductance values can be compared to earlier published data [142]. For other analytical methods for field analysis of WFNA see also [143, 144]. The determination of traces of NO_2 in WFNA uses the same methods as the determination of larger concentrations of NO_2 in RFNA and will be discussed in chapter “Red Fuming Nitric Acid”.

4.3.2 Analysis of Corrosion Products in WFNA

Soluble corrosion products remain after evaporating a sample of WFNA to dryness and will be weighed and can be analyzed if needed. Sometimes metal salts, in particular nitrates of transition metals, are added to nitric acids on purpose to achieve shorter ignition delays with hypergolic fuels. These salts also need to be analyzed for quality control.

4.3.3 Analysis of Corrosion Inhibitors in WFNA

Nitric acid may contain hydrogen fluoride as a corrosion inhibitor. The fluoride content of WFNA or RFNA can be determined gravimetrically by precipitating lead chloride fluoride PbClF . Another method would be to neutralize the acid and determine fluoride volumetrically by titrating with thorium nitrate and using sodium alizarin sulfonate as the indicator. See also [145].

4.4 Thermal Stability and Decomposition of WFNA

4.4.1 Slow Decomposition of Nitric Acid during Storage

Pure nitric acid is not stable, but will slowly decompose to nitrogen dioxide, water, and oxygen. The decomposition of nitric acid in the heterogeneous vapor-liquid region is a kinetically complex reaction which can be explained as proceeding according to the following steps:

The summation of these steps leads to the overall stoichiometric relation

where NO_2 designates an equilibrium mixture of N_2O_4 and NO_2 . The nitrogen dioxide will stain the acid yellow. This reaction is accelerated by temperatures above 273 K (0 °C) and by light (see Section 4.6 on photolysis of nitric acid). This reaction cannot be retarded by high oxygen pressure. In an intermediate range of compositions between those of WFNA and RFNA, pressurizing the mixture with oxygen will stabilize the composition, but that is not practical. The rate of decomposition can be retarded by deliberately adding two of the decomposition products, nitrogen dioxide and water. This addition of nitrogen dioxide and water to WFNA leads to RFNA and is one of the reasons for the popularity of this oxidizer.

The slow decomposition of nitric acid has been thoroughly investigated, because it is a limiting parameter when it comes to evaluating the storability of rocket propellants. The most undesirable effect of HNO_3 decomposition is the build-up of internal pressure in storage vessels from evolution of oxygen gas, which dissolves in the liquid only to a small percentage. There have been incidents of metal drums rupturing from overpressure because they were not vented periodically during the storage of WFNA. For this reason, we are including a section on the solubility of gases in HNO_3 in this chapter (see Section 3.11). Additional data on the solubility of gases in various grades of WFNA and RFNA are included in chapter “Red Fuming Nitric Acid”, which illustrates the equilibrium decomposition pressure in a ternary diagram of $\text{HNO}_3/\text{NO}_2/\text{H}_2\text{O}$ mixtures for containers with 15% ullage.

The thermal decomposition of nitric acid vapor was studied in two glass cells of considerably different surface-to-volume ratios from 100 to 465 and the rate was followed colorimetrically as the appearance of red nitrogen dioxide [146–148]. The decomposition was ambivalent: a heterogeneous reaction at low temperatures and predominantly a fast homogeneous first-order reaction above 673 K (400 °C). The het-

erogeneous reaction was initially first order, but its rate was reduced by water or nitrogen dioxide on the surface. The heterogeneous reaction has a very low energy of activation, about 20.9 kJ/mol (5 kcal/mol). The homogeneous rate was independent of reaction products: its energy of activation was 167 kJ/mol (40 kcal/mol) or higher. A mechanism was proposed whereby nitric acid decomposed to hydroxyl radicals and nitrogen dioxide but this alternative route of decomposition via ionic intermediates which was proposed earlier was later proved wrong because it was unable to explain the kinetics of the decomposition process [149].

A detailed investigation of the decomposition process of white fuming nitric acid indicated that the decomposition proceeds via the anhydride of nitric acid, dinitrogen pentoxide, as an intermediate. The decomposition of liquid HNO_3 at temperatures of 338 and 343 K was studied by measuring the rate of dioxygen gas evolution from the system at atmospheric pressure [150]. The rate data were interpreted in terms of a unimolecular decomposition of molecular N_2O_5 , which results from the self-dissociation of HNO_3 into N_2O_5 , NO_2^+ , NO_3^- , and H_2O . The liquid phase decomposition kinetics of HNO_3 can be explained if one assumes that 3.2% of the total N_2O_5 from the self-dissociation is in the molecular form at 338 K and 5.4% is in the molecular form at 343 K.

In the later work with liquid instead of gaseous nitric acid, the thermal decomposition was studied at 328, 338, and 348 K (55, 65, and 75 °C). The rate of decomposition could be expressed in terms of the water produced by the decomposition

$$-d(\text{HNO}_3)/dt = (\text{HNO}_3)^2/[f_0^0 + S(\text{H}_2\text{O})]$$

Pseudo-activation energies were then determined for f_0^0 and S . They were -162 and -116 kJ/mol, respectively (-38.7 and -27.8 kcal/mol, respectively). The ionic mechanism previously proposed for the decomposition was found to be inadequate to explain the effects of some additives. An alternative free radical mechanism was then proposed. This mechanism was found to be more satisfactory than the ionic mechanism and gave a correlation between the liquid phase and gas phase decompositions.

A study of the kinetics of the liquid phase decomposition of HNO_3 in the temperature range from 327 to 361 K (54–88 °C) suggested that the unimolecular decomposition of N_2O_5 , which is known to exist in fuming nitric acid solutions plays a significant role in the rate-determining step [151, 152]. A rate mechanism experimentally indistinguishable from that of the N_2O_5 hypothesis involves the ionic product $[\text{NO}_2^+][\text{NO}_3^-]$. The effect of several inorganic additives, namely H_2O , N_2O_4 , N_2O_5 , KNO_3 , KHSO_4 , NOHSO_4 , H_2SO_4 and HClO_4 , on the rate of decomposition was in agreement with these postulated rate mechanisms. The inhibition of the decomposition rate by various additives tested was found to be insufficient to prevent the eventual attainment of high equilibrium pressure resulting from the decomposition of fuming nitric acid when stored in closed container for periods of about 1 month in the temperature range 327–361 K (54–88 °C). Of all the additives tested on both a molar and a weight basis, H_2O gave the most pronounced effect inhibiting HNO_3

decomposition, but of course it would also detract from its performance as a rocket propellant.

The rate of pressure increase in hermetically sealed WFNA containers with 25% ullage increased with increasing temperature (Figure 21).

Figure 21: Decomposition pressure of HNO_3 as a function of time and temperature (from Contract AF33(038)10381)

The equilibrium composition is achieved after 33 h at 344 K (71°C) or 6 h at 361 K (88°C). If the logarithm of the rate of decomposition is plotted versus the reciprocal absolute temperature, the curve is nearly a straight line, in accordance with the Arrhenius function.

Other experiments showed that the equilibrium achieved in a hermetically filled container with 11% ullage is achieved after 20 h at 347 K (76 °C) [22, 153] Figure 22.

Figure 22: Decomposition pressure of pure nitric acid as a function of time and ullage at 349 K = 76 °C (reproduced and modified from [22] Contract AF33(038)10381)
 $\frac{V_g}{V}$ = Ratio of gas space : total container volume = “ullage”

Figure 23 shows the time required to reach equilibrium as a function of the temperature for 2 different ullage volume ratios, 20 and 80% ullage. It takes longer to reach equilibrium in a drum that is only 20% full (80% ullage).

The rate of decomposition can be decreased by addition of water, but that would adversely impact the rocket performance of this oxidizer. The effects of nitrogen dioxide and water on the rate of decomposition of nitric acid will be discussed in more detail in Section 4.4.1 on the decomposition of RFNA and the selection of RFNA compositions that no longer develop oxygen overpressure during long-term storage [153, 154].

Most studies of the kinetics of liquid HNO_3 decomposition used the rate of increase of pressure as a measure of the degree of conversion. The decomposition pressure is mostly caused by oxygen, which is only sparsely soluble in nitric acid, in contrast to NO_2 which is also formed but readily dissolves in HNO_3 [85]. The pressure measurements must be corrected for the amount of oxygen that is dissolved in the liquid and no longer contributes to the gas phase pressure. The solubility of oxygen in nitric acid was already discussed in the physical properties Section 3.11.

The thermal decomposition of highly concentrated nitric acid was observed at atmospheric pressure between 273 and 333 K (0 and 60 °C) for up to 273 days. The decomposition of highly concentrated nitric acid is a second order reaction in nitric acid. The

Figure 23: Time required to reach equilibrium as a function of the temperature for two different ullage volume ratios (reproduced and modified from Contract AF33(038)10381)

activation energy for decomposition of nitric acid was 134 kJ/mol [155]. See also [156, 157].

4.4.2 Rapid Decomposition of Nitric Acid Vapor

The rate coefficient for the reaction

has been determined in mixtures of nitric acid and argon in incident shock wave experiments [158]. Quantitative OH time histories were obtained by CW narrow line width UV laser absorption of the $R_1(5)$ line at 32606.56 cm^{-1} (vacuum). The experiments were

conducted over the temperature range 990–1400 K and the pressure range 18–44 kPa (0.18–0.44 atm). The second-order rate coefficient was determined to be:

$$k_1 = 1.01 \times 10^{16} \exp(-17280/T) \quad [\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}]$$

See also [159–161]. At concentrations of 10^{-5} mol/cm^3 , the decomposition of nitric acid in shock waves is controlled by the unimolecular reaction:

the rate of which is [162]:

$$\log k = (15.2 \pm 1) - [(30.6 \pm 1.8)/2.303R] \times (1000/T) \text{ mol cm}^{-3} \text{s}^{-1}$$

4.5 Storage Stability of WFNA

Measurements of the pressure rise in sealed aluminum-61S-T6 containers, which had been filled at 294 K (21 °C) leaving only 10% ullage, as a function of the initial composition of the acid indicated that equilibrium pressure was achieved after 4 weeks of storage at 327 K (54 °C) [163]. The highest decomposition pressure (7.5 MPa = 75 atm) was observed if one started the test with pure nitric acid containing hardly any H_2O or N_2O_4 , see Figure 20 in *Encyclopedia of Oxidizers*, chapter “Red Fuming Nitric Acid”. A more detailed description of these experiments is contained in *Encyclopedia of Oxidizers*, chapter “Red Fuming Nitric Acid”.

Nitric acid tends to change in composition and to corrode containers and hardware when stored for long periods of time. The most significant changes which occur are an increase in water and soluble and non-soluble solids content. If the percentage of water appreciably exceeds 2%, the acid-fuel mixtures are no longer hypergolic. A high concentration of solids causes injector nozzle and filter clogging problems. Since both RFNA and WFNA are frequently stored for extended periods of time prior to use, a project to determine optimum storage conditions was initiated and led to the recommendation that the most stable storage conditions are a temperature of 333–348 K (60–75 °F), and a maximum drum pressure of 345 kPa (50 psi) [164]. See also [165].

4.5.1 Stabilizing Additives to Nitric Acid

It has been attempted to delay the decomposition of nitric acid by dissolving stabilizing additives. The additives tested include nitrates and perchlorates of aliphatic amines. Addition of 1% $[(\text{C}_2\text{H}_5)_3\text{NH}]\text{NO}_3$ was claimed to extend the time that nitric acid can be stored at high temperature without excessive pressure build-up. For storage at 366 K (93 °C) the duration to suffer a certain degree of decomposition was extended from 28 to 72 h. Another additive was even more active: Addition of 1% $[(\text{C}_2\text{H}_5)_3\text{NH}]\text{ClO}_4$ at 366 K (93 °C) extended the duration to suffer a certain degree of decomposition from 28 to 432 h [166].

A long list of alkyl-amine and aryl-amine nitrates and $(\text{NH}_4)_2\text{S}_2\text{O}_8$ or $\text{Na}_2\text{S}_2\text{O}_8$ have been patented as stabilizers for nitric acid [167].

4.5.2 Additives Capable of Shortening the Ignition Delays

In addition to additives capable of lowering the freezing point or slowing the rate of decomposition of nitric acid, other additives have been sought, which might be capable of shortening the ignition delay of nitric acid with organic amines and hydrazines, in particular at low temperatures.

Nitric acid is not hypergolic with kerosene JP-4, but a slightly exothermic reaction occurs that is not sufficiently exothermic to lead to ignition. The exothermic reaction of nitric acid with kerosene JP-4 is said to become more exothermic if 1% $[(\text{C}_2\text{H}_5)_3\text{NH}]\text{NO}_3$ or 1% $[(\text{C}_2\text{H}_5)_3\text{NH}]\text{ClO}_4$ is added to the acid beforehand [166].

4.6 Photolysis of Nitric Acid

Because NO_2 and nitric acid, in this case in the form of peroxyntic acid, play an important role in the production and decay of photochemical smog and stratospheric clouds, the photolysis of nitric acid has been thoroughly investigated. This is less likely to occur in rocket applications. Photolysis would not be an effective method of removing nitric acid from rinse waters of a rocket test stand installation. As long as nitric acid is stored in the dark, the rocket propellant chemist does not have to worry about photolysis of nitric acid.

4.7 Radiolysis of WFNA

Radiolysis of WFNA may occur during long deep-space missions or in the vicinity of nuclear reactors, but this is not a likely scenario given the poor storability of WFNA and the lack of any plans to fly nuclear reactors again at any time soon. Radiolysis of nitrates occurs during the reprocessing of nuclear reactor fuel elements and isotope separation of the fission products.

5 Compatibility with and Corrosion Caused by WFNA

5.1 Corrosion Mechanisms in WFNA

As a strong acid, nitric acid can dissolve most metals. One is used to think that all metals will evolve hydrogen when attacked by acids. This is the case of metals dissolved by hydrochloric acid, but the reaction of nitric acid with metals goes a different route.

Instead of evolving hydrogen, the nitric acid becomes reduced to nitrous acid and nitric oxide. The reaction of nitric acid with copper shavings in the absence of oxygen is an easy method to produce nitric oxide (NO) in the laboratory:

If the apparatus is not purged of air prior to the experiment, the NO will contain varying amounts of NO₂. On the other hand, if the goal of the preparation is to obtain NO₂ instead of NO, one will allow plenty of air to pass through the apparatus to convert all NO to NO₂.

Strongly reducing metals, such as zinc or Devarda's alloy (45% Al, 50% Cu, 5% Zn), can reduce the nitrate ion all the way to ammonia. This is an antiquated method to determine nitrate in water, distilling the ammonia out of the water in a Kjeldahl apparatus and analyzing ammonia in the distillate by titration or nephelometric methods.

The corrosive action of nitric acid is extremely strong because nitric acid is both an acid and an oxidizer. Most metals, for instance iron, are converted to the nitrate salts of the metal in the highest state of oxidation of the corroded metal:

Both WFNA and RFNA are equally aggressive towards metals, RFNA being only little less aggressive than WFNA to some of the alloys. The metal nitrates formed as corrosion products either remain in solution in the acid or precipitate as a sludge or form a passivating crust on the surface of the metal. In many cases the layer formed on the metals consists not of nitrates, but their hydrolysis products, the metal oxides. A layer of insoluble metal oxide forms a protective layer and protects the underlying metal from further attack. Many metals owe their compatibility with nitric acids to this passivation phenomenon. Many metals are subjected to a special passivating pretreatment before the components are used for nitric acid service. Welded areas have to be repassivated because the passivation was lost in the heat-affected zone.

Most metals will dissolve in strong acids like nitric acid. The few metals that are compatible with concentrated nitric acid owe their resistance to the formation of an oxide passivation layer. This passivating layer will only form in concentrated acid and would dissolve in dilute acid. This often happens at tank closures where WFNA fumes mix with atmospheric moisture and become diluted and more corrosive.

The electrode potentials of aluminum and stainless steel immersed in WFNA were measured to determine their polarization characteristics under a number of conditions [168]. This included the variables of temperature, nitrogen dioxide content, water content, and acid content, as well as the effects of static versus agitated or stirred solutions. The phenomenon of anodic passivity of 2S aluminum in WFNA and the feasibility of cathodic protection of AISI Type 347 stainless steel were studied.

There is some overlap between material compatibility information discussed here for WFNA and additional information described later for RFNA. In order to obtain a complete overview, the reader should consult both sections.

5.2 Metals as Materials of Construction in WFNA

The most economic materials of construction for nitric acid systems are mostly steels and aluminum alloys. The selection of materials depends on the type of acid and will differ depending on the amount of corrosion inhibitor (hydrogen fluoride) added.

Particularly demanding requirements are imposed on components exposed to nitric acid [169]. Where metallic materials are concerned, attention must be paid not only to general corrosion, but also to intergranular and selective attack in many cases. A distinction is made between three conditions of exposure for which different materials are employed:

- Subazeotropic and azeotropic nitric acids not contaminated with oxidants,
- Subazeotropic and azeotropic nitric acids containing oxidants, such as chromates, and
- Superazeotropic, primarily highly concentrated nitric acids.

The nitric acid production industry has gained experience in the advantages and disadvantages of the materials used in the three sectors, namely austenitic chromium-nickel-(molybdenum) steels, high-silicon austenitic chromium-nickel steels, iron-silicon casting materials, glass-lined steel, glass, aluminum (alloys), titanium, zirconium, tantalum-niobium alloys, tantalum, and platinum [170]. See also [171].

Liquid droplet residues left behind after evaporation of dinitrogen tetroxide from tanks consist essentially of nitric acid. Therefore, a material compatibility study of N_2O_4 included material compatibility tests with 71% HNO_3 [172].

5.2.1 Corrosion of Steel as Material of Construction in WFNA

Steel and aluminum alloys are the main metals for use in nitric acid tanks, lines, and plumbing components. For valves and engines that must operate at higher temperatures one will prefer steels which have a better high temperature tensile strength than aluminum alloys.

Most other metals (except titanium alloys), copper, brass, bronze, silver, zinc, tin, magnesium, and their alloys are not suitable for nitric acid service. Most of these metals dissolve quickly in nitric acid under evolution of nitrous fumes (the nitric acid is reduced from the nitrogen oxidation state N^{+5} to lower oxides of nitrogen).

Stainless steel 18-8S has good corrosion resistance to nitric acid at all concentrations up to the boiling point at sea-level pressure [173].

A stainless-steel drum made from CRES 347 and used for storage and shipping of WFNA failed by leaking and was subjected to metallurgical examination [174].

The corrosion of carbon steel AISI-1020 in fuming nitric acid was less severe in the anhydrous acid [175].

Most of the investigations of steel corrosion in nitric acid solutions were done in support of designs of chemical process equipment, such as that used in the reprocessing of spent nuclear reactor fuel elements. Acid concentrations in those operations rarely go beyond 11.5 M (54%) HNO_3 [176, 177].

Iron alloys with high content of silicon ("Duriron", "Armco") can be used as storage tank materials, but they are very brittle and crack easily. They cannot be used if the nitric acid contains hydrogen fluoride as a corrosion inhibitor.

Sheet specimens of Armco iron, three types of carbon steel and stainless steel were tested to study chemical interaction of carbon and steels with dilute as well as fuming nitric acid having NO_2 contents ranging from 1 to 40% [178]. Various corrosion rate data were obtained and discussed in terms of sample weight losses and dissolution rates over periods of 120 h.

In the corrosion of stainless steels in nitric acid in heat exchangers, tests at various heat fluxes with steel surface temperature kept constant have shown that the cooler acid present at the surface under higher heat fluxes leads to slightly smaller corrosion rates than under isothermal conditions [179]. Crevice corrosion can develop under gaskets sealing the stainless-steel specimen to the test cell. This crevice corrosion can produce enhanced corrosion rates (by factors up to 100), not only on surfaces within the crevice, but also on those external to the crevice.

Three modifications of cast, low carbon stainless steels with about 15–20% Cr, 13% Ni, and 4.5–6.5% Si possess the mechanical and structural properties, castability, machinability, and weldability so that they can be used for pumps and valves in nitric acid plants [180]. Laboratory corrosion tests in boiling nitric acid between 50 and 98 mass-% HNO_3 proved the superior resistance of the Si-bearing alloys in the 90 and 98% acid compared to standard CrNi steels without Si. Comparative field tests with cast pump impellers and casings confirmed the very good corrosion resistance of the Si-bearing alloys in highly concentrated nitric acid under service conditions.

In highly concentrated HNO_3 , the presence of small amounts of HF will substantially reduce the corrosion of metallic materials. Mixtures consisting of HF and hypoaqueous nitric acid (<69.2 mass-% HNO_3) on the other hand will be strongly attacked: the metal loss will markedly increase with increasing HNO_3 and HF concentrations as well as with rising temperatures [181]. The investigation covered 12 stainless steel grades and nickel-base alloys. With constant HNO_3 content, corrosion rates rose linearly with increasing HF concentrations. With constant HF concentration (0.25 M), corrosion rates increased rapidly with increasing nitric acid concentration. (From 0.3 to 14.8 M). Alloys containing as much chromium as possible (up to 46 mass-%) will exhibit the best corrosion resistance. Alloy NiCr30FeMo (Hastelloy G-30) proved to be well suitable for service in WFNA.

The corrosion behavior of a high Si-alloyed austenitic stainless steel in RFNA was compared with CRES-316 by using linear and cyclic potentiodynamic polarization techniques, immersion corrosion test methods and scanning electron microscope (SEM) observations [182]. The inhibition effect of different concentrations of HF on the corrosion behavior of the alloys was studied. The results obtained from electrochemical measurements, immersion tests, and SEM observations were in good agreement and indicated that HF is a good inhibitor against uniform and intergranular corrosion. A high initial corrosion rate of 16.77 mpy was observed in absence of inhibitor, which was decreased to 0.24 mpy with addition of 0.6 mass-% HF. Moreover, pitting potential at the same condition increased from 1.57 to 2.31 V (vs. Ag/AgCl), indicating an improvement of the localized corrosion resistance with addition of HF inhibitor. Addition of the Si alloying element, on the one hand leads to increase the intergranular corrosion resistance but, on the other hand leads to a reduction of the general corrosion resistance. An initial corrosion rate of 1.18 mpy was obtained for CRES-316, lower than that of the Si-alloyed stainless steel.

5.2.2 Corrosion of Aluminum as Material of Construction in WFNA

Although aluminum is widely used in storage containers for WFNA, there is relatively little information on quantitative rates of corrosion and maximum operating temperatures. There is ample information on corrosion of aluminum and aluminum alloys in nitric acids with lower HNO₃ contents, but that does not apply to rocket-grade WFNA.

For maximum corrosion resistance, high purity metals are often used, such as chemically pure (CP) aluminum with higher than 99.99% aluminum content. In many cases it is not practical to produce a metal of high chemical purity because of cost considerations and because very pure metals have inadequate mechanical properties, being weak and soft. The advantage of increased corrosion resistance is thus offset by the greater thickness required and by the increased price of the superpure metal. Aluminum alloys have better strength than CP aluminum but may also be more susceptible to corrosion.

Aluminum is rapidly attacked by nitric acid at concentrations below 80%, but is better than stainless steel in hot, concentrated WFNA [173].

Corrosion characteristics of some aluminum alloys (1060, 1100, 3003, and 5052) in different concentrations of nitric acid were studied at different temperatures [183]. Alloy 3003 exhibited maximum corrosion in all the acid concentrations followed by 5052, 1100, and 1060 alloys. The corrosion rate of aluminum was found to increase in 20% and decrease with time in 70% HNO₃ solutions. In the concentration range of 20–50% of the acid, all the alloys exhibited slightly passivating tendency during the potentiostatic anodic polarization. The breakdown potential of the alloys varied inversely with temperature. The alloys exhibited negative steady-state corrosion potentials in a concentration range of 1–58% of the acid, but above this concentration

positive values of the potentials have been noted. The presence of different alloying elements may explain the different behavior of the four alloys.

A literature survey was made to examine the suitability of aluminum and aluminum alloys in contact with highly concentrated nitric acid, particularly with respect to the corrosion behavior of weld joints made using various welding processes [184]. The corrosion resistance of Al-99.5 in nitric acid was investigated as a function of temperature and acid concentrations. The linear corrosion rates were plotted in an Arrhenius diagram. Decreasing nitric acid concentrations were causing a parallel shift of the lines in the Arrhenius diagram towards higher corrosion rates. Starting with Al-99.5, the corrosion rates in nitric acid at and above 99.8% HNO_3 concentration decreased as the Al contents of the materials increased. Doping with copper should be avoided. After exposure of wrought as well as continuously cast Al and Al alloys to highly concentrated technical grade nitric acid at 303 K (30 °C) (1 year test period), the corrosion behavior of several alloys was comparable to that of pure aluminum grades.

After 10–15 years in use under harsh operating conditions, piping systems made of Al-99.5 in which highly concentrated nitric acid was flowing at a flow rate of 1 m/s exhibited flow-induced corrosion patterns [185]. In corrosion tests involving single phase flow, no relationship could be found between flow and corrosion of Al-99.5 in nitric acid of various concentrations. The following three testing methods were used: rotating disks of various configurations, rotating cylinders, and flow inside a tube. The influence of two-phase flow generated by a special mixing turbine resulted in weight losses of Al-99.5 with respect to nitric acids having concentrations of 90% to approximately 100%. In the Arrhenius diagram, the temperature dependence of corrosion data with anhydrous nitric acid was shown as a scatter band. Lower nitric acid concentrations were shifting the scatter band in the direction of higher corrosion rates. See also [186].

5.2.3 Corrosion of Titanium Alloys as Material of Construction in WFNA

Titanium and titanium alloys are resistant to corrosion by nitric acid, but can be ignited if a fresh, unpassivated metal surface (such as the shear plug in an explosive valve) is suddenly exposed to the oxidizing acid [187–189]. Titanium alloys resistant to boiling concentrated nitric acid may be alloyed with tantalum and niobium [190].

5.2.4 Compatibility Test Methods for Metals in Concentrated Nitric Acid

Candidate metals intended for use in concentrated nitric acid (WFNA or RFNA) can be tested in accordance with test method American Society for Testing and Materials (ASTM) method A279-44T3 and ASTM recommended practice A224-46 replaced by G 31 or like ASTM F359-82.

ASTM G 31-72 describes accepted procedures for laboratory immersion corrosion tests, particularly mass loss tests.

Other tests used at one time for testing steels in nitric acid are the Huey test [191] and the acidified copper sulfate test [192] recommended for the detection of intergranular attack in stainless steel, but they are somewhat removed from actual use conditions of nitric acid in a rocket, especially in the composition of the reagents used. The acidified copper sulfate reagent does not reveal knife-edge corrosion in steels stabilized with titanium or columbium. The attacking solution in the Huey test (65% HNO_3), it is not as aggressive against stainless steel as is nitric acid concentrated to 98.5%.

5.2.5 Corrosion Products in White Fuming Nitric Acid

Dilute nitric acid will corrode most metals faster than anhydrous nitric acid. Therefore, tanks that have contained fuming nitric acid should be rinsed quickly with a large excess of water and dried soon thereafter. If one allows puddles of half-diluted acid to linger anywhere in the system, dilute acid may penetrate and dissolve the passivating layer and cause severe corrosion.

Chemical, XRD, and spectrographic analyses of sludge samples collected from the sump of aluminum drums showed that most of the sludge was aluminum nitrate in the form of its hexahydrate $\text{Al}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$. This salt was not very soluble in nitric acid and its saturation concentration in WFNA was only 0.1% [193] and its solubility in RFNA was 0.3% [194]. Some stainless steels contain columbium (niobium) as a phase-stabilizing additive. The sludge in drums made from columbium-containing steels consisted of columbium carbide, silicon carbide and anhydrous nickel(III) nitrate. The sludge in drums made from other steels contained only nickel nitrate and silicon dioxide.

The examination of corroded surfaces, for instance in a drum that was used for storing nitric acid but leaked, can give valuable information about the corrosion mechanism and the cause for failure [195].

5.2.6 Galvanic Corrosion in Fuming Nitric Acids

If different metals are immersed in nitric acid and in electrical contact with each other, chances are very high that they will form a galvanic element. The metal which is the more electronegative in the series of electronegativity will suffer accelerated galvanic corrosion. The electrochemistry of galvanic corrosion can be studied in a polarimeter. Some metals will passivate, and passivation will slow down the corrosion. The polarization and corrosion of a pair of aluminum and stainless-steel electrodes in nitric acid were measured with a potentiometer [156, 196–199]. The rate of corrosion was different in stagnant and in agitated fluids and was also dependent on the velocity of the fluid stream if the metal was exposed in a propellant feed system.

5.2.7 Corrosion of Welds in Fuming Nitric Acids

The heat-affected zone adjacent to welds is particularly susceptible to corrosion by nitric acid due to residual stress and carbon precipitation in stainless steels. In the case of Fe-18Cr-10Ni stainless steel, it appears that the only grade usable in the presence of concentrated nitric acid (98.5% HNO_3) is the low-carbon Fe-18Cr-10Ni steel, with less than 0.030 mass-% carbon. Alloys stabilized with titanium or columbium showed a form of attack along the weld line known as “knife-edge corrosion” which made them fall apart completely. According to the test plan, one batch of samples was removed after 7 days, the spent acid was replaced with fresh acid and some of the specimens were tested for another 7 days in the fresh acid. Partial (2/3) immersion of double-welded coupon samples in hot 98.5% WFNA kept in a constant temperature bath at 323 K (50 °C) with a reflux condenser showed that corrosion was more severe in the heat-affected zone and depended on the thickness of the coupons [200]. Corrosion of CRES-304 alloys with carbon content from 0.040 to 0.060% resulted in the formation of deep grooves and, eventually, in perforation of the sheet extending to several millimeters on both sides of the intersection of two weld lines. The metal had become sensitized by the welding as shown by the appearance of a groove on both sides of the weld line and extending to several millimeters away from it. Variation in thickness led to different results because in the course of welding, a thin sheet will be heated more quickly and cooled more rapidly than a thick sheet. It would therefore spend less time in the zone of carbide precipitation and as a result would be less susceptible to preferential attack. The decrease in thickness in the sensitized area was 10 times greater in the 1.5-mm thick sheet than in a 0.5-mm thick sheet. With equal carbon contents, the degree of sensitization depended on the thickness of the sheet. Therefore, one should impose more severe acceptance requirements on thicker sheets or where more than two welds are to be made on the same piece.

5.3 Non-metallic Materials of Construction for Nitric Acid Service

5.3.1 Gaskets

Many organic elastomers will be attacked and destroyed by nitric acids. There are only a few elastomers that are resistant to nitric acids. The suitability of commonly used gasket materials for nitric acid applications must be verified from case to case. Many manufacturers advertise their products as “acid resistant” but that does not guarantee that the material is resistant to the strong oxidizing action of nitric acid.

Flanged metal-to-metal connections that do not need to be opened very often can be sealed with crush gaskets made from soft aluminum.

Organic elastomers resistant to nitric acids are Teflon, Kel-F, Hostaflon-TF, and Hostaflon-C2. It is surprising that IRFNA containing HF as a corrosion inhibitor will attack Kel-F more strongly than uninhibited acid. The fluoropolymers by themselves tend to cold-flow under compression. Often asbestos or glass fibers impregnated with

fluoropolymers will be shaped into gaskets for valve seats, valve stem packings, and rotary seals and similar applications to reduce the cold-flow deformations.

Polyethylene may be used only as a temporary gasket material; it lacks long-term durability. A mixture of polyethylene and polyisobutylene showed a surprisingly good resistance against RFNA [201].

Most material compatibility reports list compatibility of candidate materials with specific propellants, one propellant at a time. The literature summary by Beach inverted those lists and primary indexed the information by plastic material, with the propellant type as a secondary sorting criterion [202].

5.3.2 Lubricants for WFNA

The only lubricants acceptable for nitric acid service are chemically inert perfluorinated hydrocarbons or chlorofluorocarbons. Examples for recommended lubricants are Fluorolube, Kel-F oil or Nordcoseal-147-S. Similar lubricants are used for N_2O_4 service. Conventional greases and oils must be avoided because they constitute an explosion hazard if mixed with nitric acid [203].

6 Components for Nitric Acid Service

Many mild steel components are commonly greased for storage and shipping to prevent them from rusting during shipment and storage. Components which are used with nitric acid for the first time should be disassembled and thoroughly degreased. In the past century components intended for fuming nitric acid service were often degreased with trichloroethylene as a vapor degreaser, but this practice has been discontinued. Other degreasing techniques must be found.

Once degreased, the rust and oxide layer can be removed by dipping the components into a chromic acid bath, rinsing, and then passivating with 60% nitric acid and drying before bringing them into contact with fuming nitric acids.

6.1 Hoses

Steel-braided Teflon hoses are the best choice for flexible connections in transferring nitric acids between containers and for fueling missiles and launch vehicles. Polyethylene hoses could be used for short times and then discarded. However, polyethylenes in contact with nitric acids are a fire hazard. After all, this combination has been used in hybrid rockets!

6.2 Pumps

Pumps for nitric acid service can be made from stainless steel. The supplier's lists must be scanned thoroughly before one can find a pump proven to be reliable for fuming nitric acid service in ground service equipment (GSE). Depending on the application, one may have to resort to have a pump custom-made from specially tested alloys.

6.3 Liquid Level Gauges

Sight glasses on nitric acid storage tanks are not recommended due to the breakage potential and leakage hazard. Floats have been used as liquid level indicators.

6.4 Nitric Acid Equipment

6.4.1 Feed Systems in Flight Vehicles

Short and intermediate range missiles and launch vehicles using nitric acids are usually pressure-fed. Pressurant gases for flight vehicles are nitrogen or helium. The high-pressure pressurant tanks are heavy and bulky.

Larger missiles may realize a weight and volume saving by using an on-board gas generator instead of stored gas to expel the oxidizer from the flight tank. Two such gas generators were developed at the US Naval Ordnance Test Station [204]. Operating principles and test results of two self-regulating variable-demand gas generators were described. Red fuming nitric acid was successfully expelled by direct pressurization from a propellant tank at variable flow rates while maintaining a constant tank pressure. The results showed that a variable-demand liquid-bipropellant gas generator is feasible for a pre-packaged storable propellants missile pressurization system. This unit was throttleable and its flow rate could be varied depending on the flight status of the missile.

It has also been attempted to pressurize and expel the oxidizer by direct tank injection of a hypergolic fuel [205]. The acid in the tank will be contaminated by absorbed combustion products (water), but that can usually be tolerated.

6.4.2 Storage Containers

Storage containers for WFNA or RFNA should be made from corrosion-resistant stainless steel with as few welding seams as possible. They should not have any bottom drain valves which might leak. Instead, storage tanks for nitric acids should have a dip tube extending into a sump where the last puddle of liquid will collect, and the tank can be emptied completely. Tanks should not be filled to more than 90%, leaving 10% ullage. Because WFNA decomposes slowly and can develop an oxygen overpressure

during storage, the tanks must have a pressure relief valve. In the vicinity of the relief valve moisture from the air will condense and create a more corrosive environment than in the rest of the system.

It would be best to channel the vented gases into a duct that can be continuously purged with dry air. From there they should be fed to a scrubber or a tall vent stack. Similar precautions are recommended for RFNA.

6.4.3 Nitric Acid Storage Facility Layout

Nitric acid tanks should not be exposed to direct sunlight but should be protected from sun and weather in a well-ventilated aluminum sheet-metal roofed storage shed. The building construction must avoid combustible materials such as wood, tar paper or rubber. Spilled nitric acid might autoignite in contact with combustible materials.

Each storage tank should be placed into a concrete-lined catch basin that can contain 110% of the capacity of the tank. It would be good practice to always keep one tank unit empty as a stand-by unit in case one of the other units starts leaking.

If WFNA nitric acid is shipped and stored in drums, the drums should be stored such that the bung is in the top position. When opening the bung plug, one must wear full body protection because the contents may have developed an overpressure during storage and the liquid may spray out when the drum is first opened.

6.4.4 Maintenance and Lay-up of Nitric Acid Facilities

Test facilities with nitric acids often suffer more corrosion during idle periods than during their actual use. Residual oxidizer in liners, valves, filters, and sumps may gradually be diluted by absorbed moisture and become more corrosive. It has been considered to neutralize surface acid films during lay-up of nitric acid facilities by passing ammonia gas through the system [206].

7 Toxicity of WFNA

The fumes emitted by WFNA (remember where the letter F in WFNA comes from!) are extremely irritating to mucous membranes of the nose and eyes and are immediately noticeable. Extended exposure to WFNA fumes will damage the respiratory tract and the lung tissues. As a result, the symptoms are cough, chronic cough, bronchitis, and bronchial dilation bronchiectasis.

All nitric acid compositions (WFNA, RFNA, or MA) cause severe chemical burns when spilled on the skin instantly within a fraction of a second. It is extremely important to flush spattered nitric acid off the skin with copious amounts of water as fast as possible. Otherwise the acid will eat into the flesh and cause deep and slowly healing wounds. Rinsing the exposed skin with water should be continued for at least 15 minutes, followed by treatment with dilute sodium bicarbonate solution to neutral-

ize residual acid. Skin that has been exposed to nitric acid turns persistently yellow. This color is caused by nitrated aromatic rings in proteins in the skin. Yellow xanthoproteic acid is formed when nitric acid contacts epithelial cells and is indicative of inadequate safety precautions when handling nitric acid. The color persists until the skin peels off.

Concentrated nitric acid as encountered during normal analytical laboratory use contains only 70 mass-% HNO_3 and is not as dangerous as WFNA. Nevertheless, nitric acid spilled on the skin or fingernails will cause a yellow stain due to the formation of xanthoprotein which persists for several weeks.

Nitric acid (like all acids) splattered in the eyes will permanently damage the cornea and can lead to blindness. If nitric acid is accidentally splattered into the eye, one must immediately rinse with lots of water for at least 15 min. and consult a physician soon thereafter. Eye wash fountains are a requirement anywhere where nitric acid is handled in large quantities.

7.1 Maximum Allowable Exposure Levels of WFNA

The National Institute for Occupational Safety and Health (NIOSH) recommended exposure limits (REL) time-weighted average (TWA) for WFNA HNO_3 vapors is 2 ppm (5 mg/m^3) with a permissible short-term spike of 4 ppm (10 mg/m^3). The Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) TWA is 2 ppm (5 mg/m^3).

The original NIOSH (Standards Completion Program, SCP) immediately dangerous to life and health (IDLH) for WFNA was 100 ppm. The chosen IDLH was based on older information that pulmonary edema may result from an exposure of 100–150 ppm for only 0.5–1 h. The revised IDLH is 25 ppm [207, 208]. This may be a conservative value due to the lack of relevant acute inhalation toxicity data for workers.

7.2 Protective Clothing for Safe Handling of WFNA

Commonly used clothing made from natural or synthetic fibers is quickly destroyed by nitric acid and in extreme cases spilled acid may even lead to ignition of the combustible fabric. Protective clothing for handling of nitric acids consists of a helmet with face splash shield, gas mask or supplied air, apron, arm-length gloves, and PVC-coated boots. Ordinary vulcanized rubber boots provide only insufficient protection against nitric acids. Protective clothing can be made from polymer fiber fabric coated with PVC or Teflon. The area where nitric acids are handled must have easily accessible safety showers and eye-wash fountains. A comprehensive summary of protective clothing for all types of corrosive chemicals, and the hazards of permeation of aggressive chemicals through the protective clothing during use, is provided in [209, 210].

8 Safe Handling of WFNA

8.1 Spill Containment and Neutralization

Nitric acid spills can be flushed with copious amounts of water before the diluted acid can be neutralized with lime suspensions or caustic soda solutions. The first responder personnel must wear full protection with gas masks or self-contained breathing apparatus because the spilled concentrated acid (in particular RFNA) will warm up and release copious amounts of nitrous fumes when first contacted with a water spray.

The diluted acid rinses can be neutralized with 5% sodium hydroxide or 5% sodium carbonate or sodium bicarbonate solution before the water is allowed to drain to a public sewer system. Some public sewer systems do not allow nitrates, even if it is neutral pH. The alkaline solutions should be kept away from aluminum components because they will attack aluminum, potentially worse than acids. Other neutralizing agents tested include calcium carbonate powder or potassium carbonate solutions [211].

At one time (a long time ago) it was recommended to reduce the NO_2 -formation during treatment of RFNA spills by adding 70% sodium dichromate ($\text{Na}_2\text{Cr}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$) to the spill [212]. The oxidizer was supposed to convert nitrous acid to nitric acid and reduce the NO_2 evolution. In view of the current restrictions in flushing hexavalent chromium down the drain this is not a good practice. Additional information on the handling of nitric acids can be obtained from the following references listed in Table 41.

Table 41: Literature summaries on safe handling of fuming nitric acids.

8.2 Nitric Acid Transfer Operations

The GSE transfer of nitric acids can be performed by pumps or pressurized gas, depending on the scale of the operation. Larger facilities will use pumps, smaller facilities may use compressed gas transfer. Pressurizing gases include dry, oil-free com-

pressed air, nitrogen, argon or helium. The fumes vented from the tank being filled will need to be channeled into an exhaust duct leading to a scrubber or a tall vent stack.

At the time when the AGENA upper stages and the LANCE missile were still in use, the USAF had developed tank cars that would use pumps for transfer between the tank cars and stationary facilities [221].

9 Gelled Nitric Acids

Gelled propellants are non-Newtonian fluids and therefore exhibit a non-linear relationship between the stress and deformation rate. Depending on the gelling agent used, gelled propellants may also have a finite yield stress. Stresses applied to the fluid below the yield stress will not cause the fluid to flow but they deform like a solid. Numerous rheological models for non-Newtonian fluid mechanics exist and the choice of rheological model for a particular fluid depends on how well they match experimental data.

One of the potential benefits of gelled liquid fuels is that gelled liquid fuel propulsion systems in missiles can meet insensitive munitions (low vulnerability ammunition, IM-LOVA) safety criteria, while many of the solid propellant missiles currently in service cannot. Extensive safety testing, in particular cook-off behavior has been done with gelled propellant propulsion systems.

Like efforts with other rocket propellants, nitric acids have been gelled as a method to prevent or slow down leakage during storage or sloshing in a rapidly moving missile. Most of the gelling effort has been devoted to RFNA and IRFNA and only few investigators have attempted to produce WFNA gels. In either case, the selection of gelling agents for nitric acids is limited by the reactivity of most organic gelling agents with nitric acid. Organic gelling agents like those used for gelling fuels would rapidly be destroyed in fuming nitric acids. That leaves mostly the inorganic gelling agents, which have the necessary chemical resistance but will not improve the rocket performance properties of WFNA or RFNA. The inorganic gelling agents like fumed silica will add inert ballast to the propellant, will form troublesome residues in places where they interfere with the operation of the rocket engine, and may settle out during long-term storage. Despite half a century of research and development of gelled hypergolic bipropellants, substantial amounts of money invested in demonstration programs, these gelled propellants have not found any practical application and have not yet flown in a fielded, mass-produced missile.

9.1 Gelled White Fuming Nitric Acid

Rheological characterization of fuming nitric acid gel was performed in low-shear and high-shear rate ranges using Brookfield and capillary viscometers [222]. The gel behaved as a pseudoplastic thixotrope. There is also a section on gelled red fuming nitric acid in chapter “Red Fuming Nitric Acid”. The rheologic properties of these gelled nitric acids are very similar.

List of Acronyms

1,1-DP	1,1-bis(difluoroamino)propane
1,2,2-TP	1,2,2-tris(difluoroamino)propane
1,2-DP	1,2-bis(difluoroamino)propane
1,3-DP	1,3-bis(difluoroamino)propane
1-DB	1-difluoroaminobutane
2,2-DP	2,2-bis(difluoroamino)propane
2,3-DB-1	2,3-bis(difluoroamino)butane
2-DB	2-difluoroaminobutane
2-EHN	2-ethylhexyl nitrate
2-NDPA	2-nitrodiphenylamine
ABL	airborne laser
ABL	Allegheny Ballistics Laboratory
ABMA	Army Ballistic Missile Agency (Huntsville, AL)
ABS	acrylonitrile butadiene styrene (a polymer)
ACS	attitude control system
ACGIH	American Conference of Governmental Industrial Hygienists
ADN	ammonium dinitramide
AFRL	Air Force Research Laboratory, Edwards AFB
AI	acceptability index
AIAA	American Institute of Aeronautics and Astronautics
AIT	autoignition temperature
AM1	Austin Model 1 = AM1
AN	ammonium nitrate
AP	ammonium perchlorate
ARC	accelerating rate calorimeter
ATO	assisted take-off (propulsion system)
ATR	attenuated total reflection (spectroscopy)
BAM	Bundesanstalt für Materialforschung und -prüfung (German Federal Institute for Material Research and Testing)
BAMAG	Berlin-Anhaltische Maschinenbau A.G.
BASF	Badische Anilin und Soda Fabrik
BDE	bond dissociation energy
BEI	biological exposure index (toxicity)
BET	Brunauer-Emmet-Teller (surface area)
BKW	Becker-Kistiakowsky-Wilson (equation of state)
BOL	beginning of life
BuNENA	<i>n</i> -butyl- <i>N</i> -(2-nitroxyethyl)nitramine
CARS	coherent anti-Stokes Raman spectroscopy
CAS RN	Chemical Abstracts Service Registry Number

ccCA	correlation consistent composite approach (a computational method)
CCSD	coupled cluster singles and doubles (method)
CEA	Chemical Equilibrium with Applications (a computer program)
CFD	compressible fluid dynamics
CGA	Compressed Gas Association
CGS	centimeter gram second system (system of units)
CISD	double excitation configuration interaction (method)
C-J	Chapman-Jouguet
CMDB	composite modified double base (propellant)
CNDO	Complete Neglect of Differential Overlap
CNT	carbon nanotube
COIL	chemical oxygen iodine laser
CPIA	Chemical Propulsion Information Agency
CPIAC	Chemical Propulsion Information Analysis Center
CRES	corrosion resistant eutectic steel
CRT	cathode ray tube
CSB	US Chemical Safety and Hazard Investigation Board
CW	continuous wave (laser)
DARPA	Defense Advanced Research Projects Agency
DATB	1,3-diamino-2,4,6-trinitrobenzene
DDP	2,2-bis(difluoroamino)propionitrile
DDT	deflagration-to-detonation transition
DEGDN	diethylene glycol dinitrate
DFAP	1,1,3,5,5-pentanitro-1,5-bis(difluoroamino)-3-azapentane
DFT	density functional theory
DIN	2-difluoroamino-2-methylpropionitrile
DINA	<i>N,N</i> -bis(β -nitroxyethyl)nitramine
DIPAM	dipicramid
DNA	deoxyribonucleic acid
DNA	dinitroamine
DSC	differential scanning calorimetry
DTA	differential thermal analysis
DZP	double zeta plus polarization (basis set)
EDAX	energy dispersive X-ray analysis
EGDN	ethylene glycol dinitrate
EGMN	ethylene glycol mononitrate
EPA	Environmental Protection Agency
EPR	electron proton resonance (spectroscopy)
EPR	electron paramagnetic resonance (spectroscopy)
EOL	end of life
ERL	Explosives Research Laboratory of the National Defense Research Committee

ESA	European Space Agency
ESD	electron stimulated desorption
ESD	electrostatic discharge
ESR	electron spin resonance
ESR	electron spin resonance (spectroscopy)
FEP	fluorinated ethylene propylene (polymer)
FOI	Totalförsvarets forskningsinstitut (Swedish Defence Research Agency)
FTIR	Fourier transform infrared (spectroscopy)
GAP	glycidyl azide polymer
GC	gas chromatography
GC/MS	gas chromatography combined with mass spectrometry
GEO	geostationary Earth orbit
GTO	geostationary transfer orbit
GLC	gas liquid chromatography
GLYN	glycidyl nitrate
GSE	ground service equipment
GTN	glycerol trinitrate
HAN	hydroxylammonium nitrate
HAP	hydroxylammonium perchlorate
HBO	hyperbaric oxygen
HDA	high density acid
HEDM	high-energy density material
HETP	height equivalent to a theoretical plate
HF	Hartree–Fock (method)
HH	hydrazine hydrate
HH100	hydrazine hydrate 100% N ₂ H ₅ OH
HMX	1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane
HNDZ	1,3,3,5,7,7-hexanitro-1,5-diazacyclooctane
HNF	hydrazinium nitroformate
HNFX	3,3,7,7-tetrakis(difluoroamino)octahydro-1,5-dinitro-1,5-diazocine
HNS	hexanitrostilbene
HOF	heat (enthalpy) of formation
HP1	hydrazinium(1+) perchlorate
HP2	hydrazinium(2+) perchlorate
HPE	1,2,3,5,6,7-hexakis(difluoroamino)-4-oxaheptane
HPLC	high-performance liquid chromatography
HREELS	high resolution electron energy loss spectroscopy
HTP	high text peroxide
HTPB	hydroxyl terminated polybutadiene
HVD	high velocity detonation
IBA	1,2-bis(difluoroamino)-2-methylpropane
ICP	inductively coupled plasma (source for emission spectroscopy)

ICT	Fraunhofer Institute of Chemical Technology
ID	inner diameter
ID	internal diameter
IDLH	immediately dangerous to life or health
IEDs	improvised explosive devices
<i>i.p.</i>	intraperitoneal (injection)
IPA	<i>iso</i> -propyl alcohol
IR	infrared
IRFNA	inhibited red fuming nitric acid
Isp	specific impulse
ISRU	In-Situ Resource Utilization
IUPAC	International Union of Pure and Applied Chemistry
<i>i.v.</i>	intravenous (injection)
JANAF	Joint Army Navy Air Force
JANNAF	Joint Army Navy NASA Air Force
JATO	jet-assisted take-off (propulsion system)
JCZ	Jacobs-Cowperthwaite-Zwisler (equation of state)
JWL	Jones-Wilkins-Lee (equation of state)
JSC	Johnson Space Center, Houston (NASA)
KHT	Kihara-Hikita (equation of state)
LAD	liquid acquisition device
LANL	Los Alamos National Laboratory
LCAO	Linear Combination of Atomic Orbitals
LCH	Low Cost Hydrazine (type of Aerojet catalyst)
LC50	lethal concentration 50%
LD50	dose that is acutely lethal to 50% of the animals exposed to it
LFL	lower flammability limit
LJD	Lennard-Jones Devonshire (equation of state)
LOVA	low vulnerability ammunition
LOX	liquid oxygen
LOZ	liquid ozone
LVD	low velocity detonation
m/e	mass-to-charge ratio (in mass spectrometry)
MA	mixed acid
MAO	monoamine oxidase
MATB	monoamino-2,4,6-trinitrobenzene
MEMS	M icro E lectro M echanical S ystems
MMH	methylhydrazine
MNDO	modified neglect of diatomic overlap
MO	molecular orbital
MON	mixed oxides of nitrogen
MP2	Møller-Plesset (perturbation theory)

MRMP2	Multi-Reference Second-Order Perturbation Theory
MS	mass spectrometry
MSFC	Marshall Space Flight Center (NASA)
MTA	mass spectral thermal analysis
NAAQS	National Ambient Air Quality Standard
NACA	National Advisory Committee for Aeronautics
NADPH	nicotinamide adenine dinucleotide phosphate
NASA	National Aeronautics and Space Administration
NBP	normal boiling point
NBS	National Bureau of Standards (now NIST)
NF	trinitromethane
NFPA	2,3-bis(difluoroamino)propyl acrylate
NG	glycerol trinitrate (misnamed nitroglycerin)
NIMMO	3-nitratomethyl-3-methyloxetane
NIOSH	National Institute for Occupational Safety and Health
NIST	National Institute of Standards and Technology
NM	nitromethane
NMR	nuclear magnetic resonance (spectroscopy)
NOEC	no observed effect concentration (toxicity)
NOL	Naval Ordnance Laboratory
NONA	2,2',2'',4,4',4'',6,6',6''-nonanitro-1,1':3',1''-terphenyl
NPN	<i>n</i> -propyl nitrate
NPSH	net positive suction head
NTO	dinitrogen tetroxide
OB	oxygen balance
OD	outer diameter
OI	oxygen index
OMS	orbital maneuvering system
OPE	1,2,2,5,9,9,10-octakis(difluoroamino)-4,7-dioxadecane
OSHA	Occupational Safety and Health Administration
PAP	porous ammonium perchlorate
PBAN	polybutadiene acrylonitrile
PBX	plastic bonded explosive
PCDE	poly(1-cyano-2-difluoroamino)-2,3-epoxyethane
PCRL	Princeton Combustion Research Laboratory
PCTFE	polychlorinated tetrafluoroethylene
PCUK	Produits Chimiques Ugine Kuhlmann (absorbed into Arkema)
PEG	polyethylene glycol
PEL	permissible exposure limit
PES	photoelectron spectroscopy
PETN	pentaerythritol tetranitrate
PFA	perfluoroalkoxy alkane (polymer)

PFG	perfluoroguanidine
PGDN	propylene glycol dinitrate
PMD	propellant management device
PM3	parametric method 3 (quantum mechanics)
PMR	proton magnetic resonance (spectroscopy)
PTFE	polytetrafluoroethylene
PVC	polyvinyl chloride
PVT	Pressure-Volume-Temperature
PYX	2,6-bis(picrylamino)-3,5-dinitropyridine (PYX)
RCS	reaction control system (also roll control system)
RDX	1,3,5-trinitro-1,3,5-triazacyclohexane
REL	recommended exposure limit
RFNA	red fuming nitric acid
RLPG	regenerative liquid propellant gun
RMS	root mean square (calculation method)
RNFX	5,5-bis(difluoroamino)hexahydro-1,3-dinitropyrimidine
RSD	relative standard deviation
SCF	self-consistent field (molecular orbital calculations)
SCP	Standard Completion Program
SEM	scanning electron microscope (microscopy)
SEOS	solid electrolyte oxygen separator
SPEGL	short-term public emergency guidance level
SRI	Stanford Research Institute
STEL	short-term exposure limit
STP	standard temperature and pressure (273 K and 101 kPa)
STS	Space Transportation System (Space Shuttle)
SYEP	5,5-bis(difluoroamino)-1,9-bisdinitro-1,9-difluoro-3,7-dioxanonane
SYFO	2,2-bis(difluoroamino)-bis(5-fluoro-5,5-dinitro)pentyl formal
TATB	1,3,5-triamino-2,4,6-trinitrobenzene
TBD	<i>tert</i> -butyldifluoroamine
TEA	triethanolamine
TEGDN	triethylene glycol dinitrate
TGA	thermogravimetric analysis
TLV	Threshold Limit Value
TMEA	2,3-bis(difluoroamino)-2-methyl-butane
TMETN	trimethylolethane trinitrate
TNB	trinitrobenzene
TNETB	2,2,2-trinitroethyl-4, 4,4-trinitrobutyrate
TNM	tetranitromethane
TNO	Nederlandse Organisatie voor Toegepast Natuurwetenschappelijk Onderzoek
TNT	2,4,6-trinitrotoluene

TOFLOX	trioxygen difluoride in liquid oxygen
TRL	technical readiness level
TSCA	Toxic Substances Control Act
TSI	thermal stability index
TVOPA	1,2,3-tris[1,2-bis(difluoroamino)]ethoxy propane
TWA	Time Weighted Average (toxicity)
TZP	triple-zeta plus polarization (basis set)
UDMH	unsymmetrical dimethylhydrazine
UFL	upper flammability limit
USBM	United States Bureau of Mines
UV	ultraviolet
VST	vacuum stability test
WFNA	white fuming nitric acid
WHO	World Health Organization
WSTF	White Sands Test Facility (JSC, NASA)
WW-II	World War II
XPS	X-ray photoelectron spectroscopy
XRD	X-ray diffraction
Z-TACOT	1,3,7,9-tetranitro-6H-benzotriazole[2,1-a]benzotriazole-5-onium inner salt

Acknowledgments

The publication of this Encyclopedia has been made possible with the help from many individuals whose help is gratefully acknowledged. I want to thank Professor Dr. Thomas Klapötke of the Ludwig-Maximilians University of Munich, Germany, for writing the Foreword for the Encyclopedia and for reviewing several chapters of the book. I thank Dr. Karin Sora, Vice President Science, Technology, Engineering and Mathematics (STEM) of De Gruyter Publishers in Berlin, Germany, for the initiative to get this project started. The project was overseen by Dr. Bettina Noto, Senior Manager, of De Gruyter Publishers in Berlin, Germany. The tedious copyediting process was directed by Dipl.-Ing. Yvonne Schlatter at le-tex publishing services GmbH in Leipzig, Germany. Mr. Niklas Wingborg of FOI Sweden has reviewed and annotated the chapter on dinitramide oxidizers. My colleague Dr. Dieter Zube of Aerojet Rocketdyne in Redmond, WA, has reviewed sections of the introduction to the book. The In-Space Communications department of Aerojet Rocketdyne has provided a photo of the first 3-D printed Aerojet Rocketdyne RL-10 thrust chamber undergoing hot-fire testing with LOX/LH2 in West Palm Beach, Florida, which now decorates the covers of the first five volumes of Encyclopedia of Oxidizers. Numerous colleagues and organizations granted special request copyright permissions to reproduce images from their publications in my books. Many copyright permissions for reproduction of other images were obtained through Copyright Clearance Center with special privileges as an International Association of Scientific, Technical and Medical Publishers (STM) signatory member. My son Andreas Schmidt has drawn many of the illustrations and his skillful artwork is thankfully acknowledged. My wife Hildegard Schmidt has assisted in applying manuscript formatting changes using a computer word processor. Librarians at the Library of the University of Washington (UW), Seattle, WA, were of great help in granting use of the expansive collections of the UW library and in providing on-line access to data bases. Thanks go to the staff at U.S. Department of Defense, Defense Office of Prepublication and Security Review (DOPSR) in the Pentagon for reviewing and clearing the manuscript for public release.

Eckart W. Schmidt
